Calcium deficiency can be primary or secondary, but in both cases, the end result is a type of osteodystrophy, with the specific disease depending largely on the species and age of the animals affected.

SYNOPSIS
Etiology Primary dietary deficiency of calcium is uncommon. Secondary calcium deficiency can be induced by marginal calcium intake and high phosphorus intake.

EPIDEMIOLOGY
Calcium deficiency is a sporadic disease occurring in particular groups of animals rather than in geographically limited areas. Although death does not usually occur, there can be considerable loss of function and disabling lesions of bones or joints.

Horses in training, cattle being fitted for shows, and valuable stud sheep are often fed artificial diets containing cereal or grass hays that contain little calcium and grains that have a high content of phosphorus. The secondary calcium deficiency that occurs in these circumstances is often accompanied by a vitamin D deficiency because of the tendency to keep animals confined indoors. Pigs are often fed heavy concentrate rations with insufficient calcium supplement. Dairy cattle can occasionally be fed similarly imbalanced diets, the effects of which are exaggerated by high milk production.

There are no well-established records of calcium deficiency in grazing cattle, but there are records of low calcium intake in feedlots accompanied by clinical osteodystrophy. There is also a well-recognized field occurrence of calcium deficiency in young sheep in southeast Australia. Outbreaks can affect many sheep and are usually seen in winter and spring, following exercise or temporary starvation. In most outbreaks, the characteristic osteoporosis results from a long-term deprivation of food as a result of poor pasture growth. Occasional outbreaks occur on green oats used for grazing. The calcium intake in some cases is as low as 3 to 5 g/week in contrast to the requirement of 3 to 5 g/d. Sheep in the Kalahari Desert develop osteoporosis as a result of low calcium intake and low-grade fluorosis.7 Goats deficient in calcium, phosphorus, and vitamin D develop osteoporosis.7 Copper deficiency is associated with osteoporosis in young sheep.

High protein intake and rapid growth have been suggested as contributory factors in the development of skeletal problems in young horses (developmental orthopedic disease [DOD]). The cause of DOD in young horses is multifactorial and related to mineral imbalances in the diet, genetic predisposition, trauma, and maternal and foal nutritional status. For instance, wither height at 30 days of age, age of the mare, breed, regularity of exercise, Ca/P level in the mare and foal rations, group size in pasture, and the type and frequency of handling were identified as risk factors for DOD in foals in France.8 Although excessive energy intake is sometimes blamed, a concentration of dietary protein of 20%, which is significantly above the National Research Council (NRC) recommended level of 14%, is neither helpful nor harmful to growing horses. The high-protein diet did not affect the rate of growth, height, and circumference of cannon bones compared with horses receiving the lower 14% diet. The high-protein diet did not...
This is typical of the disease as it occurs in young sheep in southeast Australia. Attention is drawn to the presence of the disease by the occurrence of tetany, convulsions, and paresis, but the important signs are ill-thrift and failure to respond to anthelmintics. Serum calcium levels will be as low as 5.6 mg/dL (1.4 mmol/L). There is lameness, but fractures are not common even though the bones are soft. A simple method for assessing this softness is compression of the frontal bones of the skull with the thumbs. In affected sheep, the bones can be felt to fluctuate.

Pigs fed on heavy concentrate rations may develop a hypocalcemic tetany, which responds to treatment with calcium salts. Tetany may also occur in young, rapidly growing cattle in the same circumstances.

Experimentally, feeding young lambs a diet low in calcium and phosphorus for 12 weeks results in soft and pliable ribs with thickening of the costochondral junctions, reduction in feed intake by about 34%, significant changes in plasma calcium and phosphorus concentrations, and changes in dry matter digestibility. Feeding repletion diets results in complete remineralization of rib bones but only partial remineralization of the metatarsal bones.

Nutritional factors other than calcium, phosphorus, and vitamin D can be important in the production of osteodystrophies, which also occur in copper deficiency, fluorosis, and chronic lead poisoning. Vitamin A is also essential for the development of bones, particularly those of the cranium.

CLINICAL FINDINGS

The clinical findings, apart from the specific syndromes described later, are less marked in adults than in young animals, in which there is decreased rate or cessation of growth and dental maldevelopment. The latter is characterized by deformity of the gums, poor development of the incisors, failure of permanent teeth to erupt for periods of up to 27 months, and abnormal wear of the permanent teeth as a result of defective development of dentine and enamel, occurring principally in sheep.

A calcium deficiency can occur in lactating ewes and suckling lambs, whose metabolic requirements for calcium are higher than in dry and pregnant sheep. There is a profound fall in serum calcium. Tetany and hyperirritability do not usually accompany hypocalcemia in these circumstances, probably because it develops slowly. However, exercise and fasting often precipitate tetanic seizures and parturient paresis in such sheep.

In an uncomplicated nutritional deficiency of calcium in sheep, there is only a slight reduction in the radioopacity of bone, in contrast to sheep with a low phosphorus and vitamin D status, which show marked osteoporosis. The response to dietary supplementation with calcium is also of diagnostic value.

Necropsy findings

True primary calcium deficiency is extremely rare, but when it does occur, severe osteoporosis and parathyroid gland hypertrophy are the significant findings. The cortical bone is thinned, and the metaphyseal trabeculae appear reduced in size and number. The ash content of the bone is low because the bone is resorbed before it is properly mineralized.

Calcium deficiency secondary to other nutritional factors is common and typically induces the form of osteodystrophy known as osteodystrophia fibrosa (see subsequent description). In most instances, the confirmation of a diagnosis of hypocalcinosis at necropsy includes an analysis of the diet for calcium, phosphorus, and vitamin D content.

Samples for confirmation of diagnosis

- Toxicology—long bone (ASSAY [ash]); feed (ASSAY [Ca] [P] [Vit D])
- Histology—formalin-fixed section of long bone (including metaphysis), parathyroid (LM)

Differential diagnosis

A diagnosis of calcium deficiency depends on proof that the diet is, either absolutely or relatively, insufficient in calcium, that the lesions and signs observed are characteristic, and that the provision of calcium in the diet alleviates the condition. The diseases that may be confused with calcium deficiency are described under the diagnosis of each of the specific disease entities.

The close similarity between the dental defects in severe calcium deficiency of sheep and those occurring in chronic fluorosis may necessitate quantitative estimates of fluorine in the teeth or bone to determine the cause.

Treatment

The response to treatment is rapid, and the preparations and doses recommended here are effective as treatment. Parenteral injections of calcium salts are advisable when tetany is present. When animals have been exposed to dietary depletion of calcium and phosphorus over a period of time, it is necessary to supplement the diet with calcium and phosphorus during dietary mineral repletion.

Control

The provision of adequate calcium in the diet, the reduction of phosphorus intake where it
PHOSPHOROUS DEFICIENCY

SYNOPSIS

Etiology Usually a primary deficiency in the diet; may be conditioned by vitamin D deficiency.

Epidemiology Primary phosphorus (P) deficiency occurs in arid regions with low phosphorus content in soil. Most commonly chronic, but transition and acute P deficiency thought to occur in lactating dairy cattle in early lactation. Occurs under range conditions in beef cattle and sheep. Occurs in pigs not supplemented with sufficient phosphorus.

Signs Feed intake depression and anorexia are most commonly encountered sign with chronic P deficiency. Young animals grow slowly and develop rickets. Adults develop osteomalacia, unthriftiness, weight loss, reduced feed consumption, reluctance to move, leggy appearance, and fractures. Impaired milk production, growth rate, and fertility, presumably due to energy and nutrient deficiency as a result of feed-intake depression. Recency and acute intravascular hemolysis (postpartum hemoglobinuria) in high-producing cows in early lactation have empirically been associated with hypophosphatemia and P depletion.

Clinical pathology Serum inorganic phosphorus. Phosphorus content of diet.

Necropsy findings Rickets and osteomalacia; lack of mineralization of bones.

Diagnostic confirmation Radiography of long bones, histology of bone lesions; bone ash analyses.

Differential diagnosis Those diseases resembling rickets and osteomalacia. Milk fever and downer cow syndrome in periparturient recumbent cattle. Other disorders associated with intravascular hemolysis in cases of periparturient hemoglobinuria.

Treatment Phosphate salts orally or intravenously, vitamin D.

Control Supplement diets with adequate phosphorus, calcium, and vitamin D.

ETIOLOGY

Phosphorus (P) deficiency occurs predominantly in arid regions of the world with low P content in soil. Phosphorus deficiency is encountered whenever the daily dietary P intake is insufficient to cover the requirements for maintenance and production and the organism has to recur to the mobilization of bone P. Under most circumstances P deficiency is chronic, and signs and symptoms associated with it occur after dietary P deprivation over months to years.

In dairy cattle, a rather acute and transient period of P deficiency is thought to occur in the first days to weeks of lactation and has been associated with recumbency and acute intravascular hemolysis in early-lactating cows. Rations with marginal P content in combination with low feed intake around calving are thought to result in inadequate P intake to cover for the suddenly increasing P requirements for milk production at the onset of lactation. The assumption that the commonly observed periparturient hypophosphatemia is an indicator for P depletion is, however, under contentious debate, and the clinical relevance of subnormal plasma inorganic phosphorus (Pi) levels in affected cows is uncertain. Pronounced hypophosphatemia is also seen around parturition in mastectomized cattle, which don't produce any milk. Furthermore, even severe hypophosphatemia is often seen in healthy fresh cows not showing any clinical signs or symptoms.

EPIDEMIOLOGY

Geographic Occurrence

Chronic P deficiency has a distinct geographic distribution depending largely upon the P content of the parent rock from which the soils of the area are derived, but also upon the influence of other factors, such as excessive calcium, aluminum, or iron, which reduce the availability of P to plants. Large areas of grazing land in many countries are of little value for livestock production without P supplementation. In New Zealand, for example, where fertilization of pasture with superphosphate has been practiced for many years, P deficiency may still occur in dairy herds because of inadequate maintenance of application over several years. Animals in affected areas mature slowly and are inefficient breeders, and additional losses as a result of botulism and defects and injuries of bones may occur. Apart from areas in which frank P deficiency is seen, it is probable that in many other areas a mild degree of deficiency is a limiting factor in the production of meat, milk, and wool.

Heavy leaching by rain and constant removal by cropping contribute to P deficiency in the soil, and the low P levels of the plant cover may be further diminished by drought conditions. Pastures deficient in P are classically also deficient in protein.

Cattle

The earliest report of naturally occurring P deficiency in grazing cattle was at Armood-vlakte in the Northern Cape of South Africa. The disease was called aphosphorosis, and animals with the disease demonstrated a depraved appetite characterized by the desire to eat wood, bones, rocks, and other such materials, a behavior known as pica. In severely affected regions, cattle often died from botulism from eating bones from old carcasses contaminated with Clastidium botulinum toxin. In advanced states of aphosphorosis, animals developed bone malformations that were associated with stiffness in

</table>
the forelegs, with a characteristic lameness referred to as "stysiekte" in South Africa, "creeps" in Texas, and "pegleg" in Australia. A survey of the mineral status of bones of cattle at abattoirs in western New South Wales, Australia, found evidence of osteodystrophy based on ash density. They represented cattle attempting to grow in a poor season, often female, in poor body-fat condition, light in body weight, and mostly from red soils known to be deficient in P.

Cattle constantly grazing pasture in the southern hemisphere appear to require somewhat less P in the diet (0.20% is probably adequate) than do higher-producing, partly housed livestock. The dietary requirements of P recommended by the NRC for beef cows weighing 450 kg may exceed the basic requirements. Over a period of several gestations, a daily allowance of 12 g of P per day per animal was deemed to be adequate for beef cows. Cattle given a P-deficient diet did not develop detectable signs of P deficiency until after 6 months of deprivation of this mineral.2

Hypophosphatemia in periparturient dairy cows is widespread, affecting at least 10% of fresh dairy cows, and it is often interpreted as a sign of dietary P deficiency in the periparturient period.1,4 Hypophosphatemia in early lactation has been associated with syndromes such as postparturient hemoglobinuria, a form of intravascular hemolysis that is thought to be caused by increased fragility of red blood cell in P-deficient states and postparturient recumbency that is not responsive to intravenous treatment with calcium salts.1,4

Sheep and Horses
Sheep and horses at pasture are much less susceptible to the osteodystrophy of P deficiency than are cattle, and their failure to thrive on P-deficient pasture is probably attributable in part to the low protein content of the pasture. In fact, there has been no clear demonstration of a naturally occurring P deficiency in sheep.

There is some limited evidence that the plasma inorganic phosphorus (Pi) levels in Thoroughbred racehorses may be related to certain feeding regimens and to racing performance. Horses fed cubed or pelleted dietary supplement have plasma Pi concentrations consistently below an accepted mean of 1.03 mmol/L (3.2 mg/dL). It is suggested that a rapid rate of passage of the ingesta may affect P absorption. Other observations indicate that some of the best track performers had significantly lower plasma Pi concentrations compared with some of the worst performers.

Pigs
A primary deficiency can occur in pigs kept in confinement and not provided with sufficient dietary P. Lactating sows are more commonly affected than growing pigs. In some situations, in the cereal grains, the phytate levels are so high and phytase levels so low that rickets and osteomalacia are common in the pig population.

Secondary Phosphorus Deficiency
Secondary P deficiency is the result of hyperparathyroidism or vitamin D deficiency. This is of minor importance compared with the primary P deficiency. A deficiency of vitamin D is not necessary for the development of osteodystrophy, although with suboptimal P intakes deficiency of this vitamin becomes critical. Excessive intake of calcium does not necessarily result in secondary P deficiency, although it may cause a reduction in weight gains, probably as a result of interference with digestion, and may contribute to the development of P deficiency when the intake is marginal. The presence of phytic acid in plant tissues, which renders phytate-P unavailable to nonruminant species, is a major consideration in pigs but of only minor importance in ruminants, except that increasing intakes of calcium may reduce the availability of phytate-P even for ruminants. Rock phosphates containing large amounts of iron and aluminum have been shown to be of no value to sheep as a source of P. A high intake of magnesium, such as that likely to occur when magnesium is fed to prevent lactation tetany, may cause hypophosphatemia if the P intake of dairy cows is already low.

PATHOGENESIS
Of the body P, 80% to 85% is located in the skeleton, where it is deposited in a metabolically inert form together with calcium as hydroxyapatite. Hydroxyapatite is the compound that provides bone with its characteristic structural rigidity and stability. Bone P also functions as an important P reservoir that can be mobilized when body requirements temporarily exceed dietary intake. The remainder of the body P is available as dissolved P that is either encountered as inorganic phosphates (Pi) or forming part of organic molecules such as phospholipids, phosphocreatine, different adenosine molecules, or various carbohydrate metabolites. Phosphorus is a predominantly intracellular mineral, of which only small amounts are located in the extracellular space. Phosphorus bound in phospholipid molecules is essential for the structural stability of cell membranes that are composed of these phospholipids. The availability of soluble Pi in the extracellular space is essential for a plethora of biochemical reactions, especially those concerned with energy metabolism and transfer. Phosphorus furthermore functions as a buffer in rumen fluid, urine, and the intracellular space. Rumen microbes that are of critical importance for ruminant nutrition are inherently dependent of adequate P supply, which is not only provided by feed but also by the salivary glands, which produce large amounts of saliva rich in P.
Primary P deficiency is common only in cattle and is associated with chronic dietary P deprivation. In the experimental production of P deficiency in beef or dairy cattle, several months to years on a P-deficient diet are necessary before clinical signs develop.

Young animals grow slowly and develop rickets. In adults there is an initial subclinical stage followed by osteomalacia. In ruminants of all ages, a reduction in voluntary feed intake is a first sign of P deficiency and is the basis of most of the general systemic symptoms to follow, which are retarded growth, weight loss, low milk yield, and reduced fertility. For example, in severe P deficiency in range beef cattle, the calving percentage has been known to drop from 70% to 20%. The development and wear of teeth are not greatly affected, in contrast with the severe dental abnormalities that occur in a nutritional deficiency of calcium. However, malocclusion may result from poor mineralization and resulting weakness of the mandible. More advanced stages of P deficiency occurring in severely P-deficient regions are associated with reluctance to move, abnormal stance, and increased incidence of bone fractures. The animals have a leggy appearance with a narrow chest and small girth, the pelvis is small, and the bones are fine and break easily. The chest is slab-sided as a result of weakness of the ribs, and the hair coat is rough and lacking in pigment. In areas of severe deficiency, the mortality rate may be high as a result of starvation, especially during periods of drought when deficiencies of P, protein, and vitamin A are severe. Osteophagia is common and may be accompanied by a high incidence of botulism.

Cows in late pregnancy often become recumbent, and although they continue to eat, they are unable to rise. Such animals present a real problem in drought seasons because many animals in the area may be affected at the same time. Parenteral injections of P salts are ineffective, and the only treatment that may be of benefit is to terminate the pregnancy by the administration of corticosteroids or by cesarean section.

A more acute form of P deficiency is thought to occur in the first days to weeks of lactation in mature, high-yielding dairy cows. Hypophosphatemia in these animals has been associated with periparturient recumbency that is unresponsive to IV treatment with calcium salts. Affected animals are recumbent but mentally alert, with normal or only slightly decreased feed intake. They continue making attempts to stand and tend to creep around.

Another condition associated with P depletion and hypophosphatemia in dairy cattle in early lactation is postparturient hemoglobinuria. The disorder affects individual mature animals in the first days to weeks of lactation and is characterized by massive intravascular hemolysis, resulting in the excretion of large amounts of hemoglobin in urine (see also the discussion of postparturient hemoglobinuria). Although sheep and horses in P-deficient areas do not develop clinically apparent osteodystrophy, they are often of poor stature and unthrifty and may develop perverted appetites. An association between low serum or plasma Pi and infertility in mares has been suggested, but the evidence is not conclusive. The principal sign in affected sows is postpartum paralysis.

**CLINICAL PATHOLOGY**

**Serum Phosphorus**

The concentration of serum or plasma Pi is the most commonly used parameter to assess the P status of an individual animal independent of the species. Although the serum Pi concentration reflects the short-term dietary P supply and the body's P pool size reasonably well, it is less suited to diagnose chronic P deficiency because compensatory mobilization of P reserves from bone tend to increase the Pi concentration in serum or plasma, thereby masking P depletion at least partially. Marked individual and diurnal fluctuations of the serum Pi concentration further complicate the interpretation of this parameter on an individual animal basis.

Serum Pi levels are affected by such factors as age, milk yield, stage of pregnancy, breed, dietary P content, time of sample collection relative to feeding, and the blood vessel from which the blood sample is collected. Rapid and pronounced changes of the serum Pi level in the range of 10% to 30% can occur as a result of sudden shifts of P from the extracellular to the intracellular space, for instance, after strenuous physical exercise or oral or parenteral administration of carbohydrates. Hypophosphatemia diagnosed in one single sample collected from one animal is therefore an unreliable indicator for the P status of that individual or a group of animals. The diagnostic value of the serum P concentration is complicated by the fact that clinical signs are not consistently observed with a certain degree of hypophosphatemia. For instance, serum Pi levels below 0.6 mmol/L (1.9 mg/dL) in cattle have been associated with intravascular hemolysis and recumbency, whereas even lower concentrations are often measured in healthy dairy cows. To obtain comparable results it is advisable to collect blood from the same blood vessel at standardized times relative to feeding.

Reference ranges for cattle given in the literature are 1.4 to 2.6 mmol/L (4.0 to 8.0 mg/dL) and 1.9 to 2.6 mmol/L (6.0 to 8.0 mg/dL) for adult and growing animals, respectively. The reference ranges for sheep and goats are 1.6 to 2.4 mmol/L (5.0 to 7.3 mg/dL) and 1.3 to 3.0 mmol/L (4.2 to 9.1 mg/dL), respectively. Juvenile and growing individuals have higher serum Pi because of enhanced intestinal Pi uptake.
presumably to provide sufficient Pi for adequate bone mineralization. The reference ranges for serum Pi for horses and swine are 1.0 to 1.8 mmol/L (3.1 to 5.6 mg/dL) and 2.1 to 3.3 mmol/L (6.5 to 10.2 mg/dL) respectively.

**Dietary Phosphorus Content**

Estimating the dietary P content is among the most reliable methods to estimate the P status of one or several animals, provided the feed intake can also be quantified. For pastured cattle, estimation of the dietary P content based on the P content in soil has been proposed. A P content in soil above 8 ppm was not associated with any signs of P deficiency, whereas negative effects on feed intake, growth, and fertility became apparent in cattle pastured for prolonged periods on soils with a P content between 7 and 8 ppm. Signs became more prominent in animals kept on soils with a P content between 4 and 6 ppm and were most severe on soils with a P content below 4 ppm.

The association between dietary P intake and the concentrations of P in feces has been explored in several studies. Although the effect of the dietary P content on the intestinal absorption rate of P is well established, neither rumen fluid samples nor fecal grab samples were found to reliably identify P-depleted animals. Specifically, when P-depleted animals show feed-intake depression, a clinical sign often associated with P deficiency, fecal output decreases. This can translate into unchanged or even increased fecal P, although the total fecal P output is decreased.

**Bone Ash Concentrations**

Determination of total bone ash concentrations and bone calcium and P concentrations from a sample of rib can provide useful diagnostic information and comparison to normal values. Nonetheless the bone P content is slow to respond to changes in dietary P supply, which means that the nutritional history has a strong impact on the mineral content of fresh bone. The P content in fresh bone is considered an excellent indicator for the body P reserves, but not for the current dietary P supply or the P pool size. Because obtaining bone biopsies is impractical under field conditions, determination of bone P content is largely restricted to postmortem examination or research.

**NECROPSY FINDINGS**

The necropsy findings are those of the specific diseases, rickets, and osteomalacia.

**DIFFERENTIAL DIAGNOSIS**

A diagnosis of phosphorus (P) deficiency depends on evidence that the diet is lacking in P and that the lesions and signs are typical of those caused by P deficiency and can be arrested or reverted by the administration of P. Differentiation from those diseases that may resemble rickets and osteomalacia is dealt with under those headings.

**TREATMENT**

For P supplementation in ruminants, either oral or parenteral treatment has been proposed. For metabolism and cell function, the organism requires P as inorganic phosphate (PO₄). Accordingly, P must be supplemented in a form that either contains phosphate or as a compound that can be hydrolysed to phosphate. Most pharmaceutical products containing P and labelled for parenteral administration in animals contain phosphate (PO₄), hypophosphite (PO₃), or organic P compounds such as toldimfos (dimethylamino-methylphenyl-phosphite) or butafosfan (butylamino-methylethyl-phosphonic acid), which the body does not appear to convert to phosphate. These compounds must thus be considered to be unsuitable for P supplementation.

The preparation of a custom-made solution either with 300 mL of distilled water containing 30 g of Na₂HPO₄ or 500 mL of deionized water containing 90 g of Na₂HPO₄ × 12H₂O, which are to be administered intravenously as a single dose to an adult cow, have been proposed in the literature (both equivalent to approximately 8 g of P) but are extra-label treatments. Both solutions are only suitable for IV administration, and their effect on the plasma Pi concentration is short lived, lasting for less than 2 hours when administered as an IV bolus.

Because of the rapid and sustained effect of orally administered P salts, this treatment route is preferred over the parenteral route. Oral administration of monosodium dihydrogen phosphate (300 g) or monopotassium dihydrogen phosphate (250 g), both providing approximately 60 g of P, were found to increase the plasma Pi concentration in hypophosphatemic dairy cows within 3 to 4 hours of treatment and for at least 12 hours. Monocalcium phosphate (250 g, also equivalent to approximately 60 g P) was less effective than monosodium phosphate and monopotassium phosphate, but more effective than dicalcium phosphate.

**CONTROL**

Phosphorus deficiencies in grazing livestock can be prevented by direct treatment of the animal through supplementing the diet or the water supply, or indirectly by approximate fertilizer treatment of the soils. Hand-fed animals are supplemented with P in their diets.

**TREATMENT AND CONTROL**

**Treatment**

*Cattle*

Monosodium dihydrogen phosphate (36 g NaH₂PO₄ dihydrate in 300 mL distilled water IV as single dose) (R-2)

**Monocalcium Phosphate**

Disodium monohydrogen phosphate (90 g Na₂HPO₄ × 12 H₂O in 500 distilled water IV as single dose) (R-2)

Monosodium dihydrogen phosphate (300 g NaH₂PO₄ PO q12h for 1 to 3 days) (R-1)

Monopotassium dihydrogen phosphate (250 g KH₂PO₄ PO q12h for 1 to 3 days) (R-2)

Monocalcium dihydrogen phosphate (250 g Ca(H₂PO₄), PO q12h for 1 to 3 days) (R-2)

Dicalcium monohydrogen phosphate (300 g CaHPO₄ × 2H₂O PO q12h for 1 to 3 days) (R-3)

Monosodium dihydrogen phosphate IM or SC (R-3)

Disodium monohydrogen phosphate IM or SC (R-3)

Butafosfan (butylamino-methylethyl-phosphonic acid) (R-3)

Toldimfos (dimethylamino-methylphenyl-phosphinate) (R-3)

**Control**

Bone meal, calcium-phosphate salts, sodium-phosphate salts, and sodium-pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt.

Fertilization of P-deficient pastures with phosphate.
recommends up to 0.42% dietary P for the highest-producing cows during the first few weeks of lactation. Several studies indicate that dietary P at 0.38 to 0.40% is sufficient for high producing dairy cows. Depending on feed ingredients, this concentration of P can be obtained with no or minimum supplementation with P of a standard North American or European dairy cow ration. Negative effects on milk yield and feed intake were observed in dairy cows fed ration with a dietary P content below 0.31% of feed dry matter over several months. Cows conserve P when feed diets low in P by reducing P excretion in feces. The transition period from late gestation to lactation presents a particular challenge for the mechanisms regulating the P homeostasis. In the last weeks of gestation, the dietary P content is often limited to reduce the risk of parturient paresis. With the onset of lactation, daily P requirements increase suddenly while daily feed intake is at a nadir. This situation may indeed result in a transiently negative P balance during the first days of lactation, which is likely to contribute to the commonly encountered hypophosphatemia in fresh cows. However, the mechanisms driving this parturient hypophosphatemia are not well understood, and the degree of P depletion in affected cows has never been examined in detail, but has rather just been extrapolated from the observed declines in plasma Pi levels. Hypophosphatemia shortly after calving is an unreliable indicator for P depletion because this decline in plasma Pi levels has not only been attributed to P losses through the mammary gland but also to hormone-induced compartmental shifts of P from the extracellular to the intracellular space.

It is deemed unlikely that increasing the amount of dietary P in late pregnancy and early lactation will be able to prevent parturient hypophosphatemia because this imbalance seems to occur secondary to hypocalcemia.

Environmental Implications of Phosphorus Feeding of Livestock

In the European Union and the United States, environmental pollution with P from cattle manure has received increased attention over the past decades, and incentives with the objective to reduce the P content in ruminant fecal material have been implemented in many countries.

Ideally, P is recycled into the soil/plant/animal system, from which only the P incorporated into the animal system escapes. In a sustainable dairy farming system, the amount of P expelled in the form of manure must be limited to the amount that crops need for maximum growth. However, because of high livestock intensities and excessive amounts of P in feed, overapplication of P from manure occurs, leading to P accumulation in the soil and finally leaching, thus causing eutrophication of surface waters. Reducing the dietary P intake of cattle has been identified as an effective way to reduce the amount of P in manure and thereby contain environmental pollution with P.

The current recommendations for dairy cattle from the NRC are to provide phosphorus at 0.32% to 0.42% of dry matter intake. These are lower than the previous recommendation of 0.5% of dry matter intake. Based on calculation of P losses and the true absorption coefficient using data on saliva production, saliva P content, and the efficiency of P absorption, the P requirement recommended for dairy cows in the Netherlands are as follows: P requirement (g/d per 600-kg cow) = 19 + 1.43 × 1 kg milk. This recommendation is up to 22% lower than the current recommendation for high-yielding dairy cows used in the United Kingdom.

Surveys in the United States revealed that dairy diets contain approximately 0.45% to 0.50% P (DM basis), an amount that is about 20% in excess of estimated requirements. A reduction of the dietary P content by 20% was estimated to result in a 25% to 30% reduction in the P content of manure and a similar reduction in the amount of land required to accommodate the manure. Phosphorus is the most expensive nutrient in typical mineral–vitamin formulations for dairy cattle. Feeding a diet containing 0.45% P versus one containing 0.55% would save about $0.05/cow daily; for a 100 cows over 1 year, this would save about $1825.00.

Simulation models of the long-term effects of changes in feeding, cropping, and other production strategies on P loading and the economics of 100-cow and 800-cow dairy farms in southeastern New York found that the most easily implemented change was to reduce the supplemented mineral P fed to that required to meet the current NRC recommended amounts, which would provide an annual increase in farm profit of about $22.00 per cow.

The overfeeding of P has important environmental implications. Phosphorus excretion increases linearly as P intake is increased above the requirement. Once P requirements are met, all of the excess dietary P is excreted in the feces. This excess P accumulates in the environment, primarily by the recycling of manure to land as fertilizer for crop production. The surface runoff of this excess P promotes the eutrophication of surface waters (eutrophication is the accidental or deliberate promotion of excessive growth of one kind of organism to the disadvantage of other organisms in the ecosystem). Therefore, close monitoring of P inputs in the livestock industry is important to reduce the risk of eutrophication of lakes and streams. Reducing dietary intake closer to the requirement will require frequent and accurate feed analysis, quantification of dry matter intake, and ration management to ensure that formulated diets are mixed and delivered to the cows properly. Phosphorus reduction will be achieved by precision of feeding of dairy cattle. Portable and rapid tests are now available to determine the level of P in dairy cattle manure. These hand-held tools can yield real-time measurements of dissolved P and total P in manure.

The effects of feeding low amounts of P to high-yielding dairy cows have been examined extensively in numerous studies. Lactating dairy cows were fed diets containing 67%, 80%, and 100%, respectively, of the P requirements recommended by the Dutch Committee on Mineral Nutrition for a period of 21 months. Nearly 5 months after the beginning of the feeding trial, the milk yield and milk lactose content of the 67% group decreased significantly. It was concluded that rations for high-yielding dairy cows should not have a P content lower than 3.0 g/kg (or 0.3%) DM. The P supply with the 80% ration was considered to be just sufficient.

The supplementation of dietary P above levels recommended by the NRC (0.38% considered adequate or 0.48% excessive) did not improve duration or intensity of estrus in dairy cows. Large lactation studies have shown that feeding P in excess of 0.37% of diet DM, which corresponds closely to the NRC P requirements, did not affect milk production, milk composition, or animal health. Digestion studies and P retention data also support the NRC recommendations.

**Beef Cattle**

There has been a notable lack of research into the P requirements of grazing beef cattle of various age groups and under varying soil and forage conditions, which has created considerable confusion and disagreement about the P requirements. The effects of P fertilizer on forage P levels and seasonal changes in P concentration are well understood, but the availability of P in different forage species, at different stages of maturity, and grown under different management schemes and environmental conditions is not well understood.

The details of the phosphorus requirements for beef cattle of various age groups are available in the NRC publication *Nutrient Requirements of Beef Cattle*, which was updated in 2000.

**Feedlot Cattle**

The P requirement of finishing feedlot calves is less than 0.16% of diet DM or 14.2 g/d. Typical grain-based feedlot cattle diets do not require supplementation of inorganic mineral P to meet P requirements. Plasma P, performance, and bone characteristics indicate that P requirements are less than the predicted requirements and should be modified. Supplementation of mineral P in finishing diets is an unnecessary economic and environmental cost for beef feedlot producers and should be discontinued.
Pigs
The estimated dietary P requirements for maximum growth and feed efficiency of pigs at 3 to 5, 5 to 10, 10 to 20, 20 to 50, 50 to 80, and 80 to 120 kg, as a percentage of diet (90% DM) are 0.70%, 0.65%, 0.60%, 0.50%, 0.45%, and 0.40%, respectively. The form in which P exists in natural feedstuffs influences the efficiency of its utilization. In cereal grains, grain byproducts, and oilseed meals, about 60% to 75% of the P is organically bound in the form of phytate, which is poorly available to nonruminant species. The biological availability of P in cereal grains is variable, ranging from less than 15% in corn to approximately 50% in wheat, which has naturally occurring phytase enzyme. The P in inorganic phosphorus supplements also varies in bioavailability. The P in ammonia, calcium, and sodium phosphates is highly available.

Phosphorus Supplementation
Bone meal, calcium-phosphate salts, sodium-phosphate salts, and sodium-pyrophosphate may be provided in supplementary feed or by allowing free access to their mixtures with salt or more complicated mineral mixtures. The availability of the phosphorus in feed supplements varies, and this needs to be taken into consideration when compounding rations. For cattle, mineral sources with the highest absorption coefficients for P are monosodium dihydrogen phosphate (absorption coefficient 0.9), ammonium phosphates and monocalcium phosphate (absorption coefficient 0.80), followed by dicalcium phosphate (absorption coefficient 0.75). The relative biological values for young pigs in terms of phosphorus are as follows: dicalcium phosphate or rock phosphate, 83%; steamed bone meal, 56%; and colloidal clay or soft phosphate, 34%. It is suggested that in deficient areas adult dry cattle and calves up to 150 kg BW should receive 225 g bone meal/week, growing stock over 150 kg BW 350 g/week, and lactating cows 1 kg weekly, but experience in particular areas may indicate the need for varying these amounts. The top dressing of pasture with superphosphate is an adequate method of correcting the deficiency and has the advantage of increasing the bulk and protein yield of the pasture, but it is often impractical under the conditions in which the disease occurs.

The addition of phosphate to drinking water is a much more satisfactory method, provided the chemical can be added by an automatic dispenser to water piped into troughs. Adding chemicals to fixed tanks introduces errors in concentration, excessive stimulation of algal growth, and precipitation in hard waters. Monosodium dihydrogen phosphate (monosodium orthophosphate) is the favorite additive and is usually added at the rate of 10 to 20 g/20 L of water. Superphosphate may be used instead but is not suitable for dispensers, must be added in larger quantities (50 g/20 L), and may contain excess fluorine. A reasonably effective and practical method favored by Australian dairy farmers is the provision of a supplement referred to as “super juice.” Plain superphosphate at a rate of 2.5 kg in 40 L of water is mixed and stirred vigorously in a barrel. When it has settled for a day, the “super juice” is ready for use and is administered by skimmin off the supernatant and sprinkling 100 to 200 mL on the feed of each cow.

VITAMIN D DEFICIENCY

SYNOPSIS
Etiology Deficiency of preformed vitamin D and, less commonly, insufficient exposure to ultraviolet solar irradiation.
Epidemiology Uncommon because diets are supplemented. Occurs in animals in countries with relative lack of UV irradiation, especially in winter months; animals raised indoors for long periods. Can occur in young grazing animals in winter months. The is marked species variation in susceptibility to effects of vitamin D deficiency.

Vitamin D deficiency is usually caused by insufficient solar irradiation of animals or their feed, or inadequate concentrations of vitamin D in rations of housed animals, and is manifested by poor appetite and growth and in advanced cases by osteodystrophy (rickets or osteomalacia).

ETIOLOGY
A lack of ultraviolet solar irradiation of the skin, coupled with a deficiency of preformed vitamin D complex in the diet, leads to a deficiency of vitamin D in tissues.

EPIDEMIOLOGY
Although the effects of clinically apparent vitamin D deficiency have been largely eliminated by improved nutrition, the subclinical effects have received little attention. For example, retarded growth in young sheep in New Zealand and southern Australia during winter months is corrected or prevented by vitamin D administration.

However, general realization of the importance of this subclinical vitamin D deficiency in limiting productivity of livestock has come only in recent years. This is partly a result of the complexity of the relations between calcium, phosphorus, and vitamin D and their common association with protein and other deficiencies in the diet. Much work remains to be done before these individual dietary essentials can be assessed in their correct economic perspective.

Vitamin D is available to animals from either or both of isomerization of 7-dehydrocholesterol (7-DHC) in the skin to vitamin D3 during exposure to ultraviolet light or ingestion of vitamin D3 or D2 in the diet.

Ultraviolet Irradiation
The intensity of ultraviolet light that reaches the skin of the animal depends on latitude and altitude. The lack of ultraviolet irradiation becomes important as distance from the
equator increases and the sun’s rays are filtered and refracted by an increasing depth of the earth’s atmosphere. Cloudy, overcast skies, smoke-laden atmospheres, and winter months exacerbate the lack of irradiation. When the incidence angle of sun striking the skin is less than 35 degrees, as occurs during winter at latitudes of 31 degrees or higher, there is insufficient penetration of ultraviolet light to convert 7-DHC to previtamin D 3.1 Reduced grazing time of cattle during summer at higher latitudes (56 degrees) is linearly associated with serum vitamin D concentrations.2 The production of vitamin D 3 by dairy cows is directly correlated with the amount of skin exposed to ultraviolet radiation, and blanketsing cows reduces vitamin D 3 production.

The effects of poor irradiation are felt first by animals with dark skin (particularly pigs and some breeds of cattle) or heavy coats (particularly sheep), by rapidly growing animals, and by those that are housed indoors for long periods. The concentration of plasma vitamin D 3 recorded in grazing sheep varies widely throughout the year. During the winter months in the United Kingdom, the levels in sheep fall below what is considered optimal, whereas in the summer months, the levels are more than adequate. There is a marked difference in vitamin D status between sheep with a long fleece and those that have been recently shorn, especially in periods of maximum sunlight. The higher blood levels of vitamin D in the latter group are probably a result of their greater exposure to sunlight. Pigs reared under intensive farming conditions and animals being prepared for shows are susceptible especially if the diet is marginal or deficient in vitamin D.1

Dietary Vitamin D

The importance of dietary sources of preformed vitamin D must not be underestimated. Irradiated plant sterols with antirachitic potency occur in the dead leaves of growing plants. Variation in the vitamin D content of hay can occur with different methods of curing. Exposure to irradiation by sunlight for long periods causes a marked increase in antirachitic potency of the cut fodder, whereas modern hay-making technique with its emphasis on rapid curing tends to keep vitamin D levels at a minimum. Grass ensilage also contains very little vitamin D.

Based on a survey of the concentrations of vitamin D in the serum of horses in the United Kingdom, the levels may be low. In the absence of a dietary supplement containing vitamin D, the concentrations of 25-OH D 3 and 25-OH D 3 are, respectively, a reflection of the absorption of vitamin D 3 from the diet and of biosynthesis of vitamin D 3.

Information on the vitamin D requirements of housed dairy cattle is incomplete and contradictory. It appears, however, that in some instances natural feedstuffs provide less-than-adequate amounts of the vitamin for optimum reproductive performance in high-producing cows.

Grazing Animals

The grazing of animals, especially in winter and on lush green feed including cereal crops, leads to a high incidence of rickets in the young. An antivitamin D factor is suspected because calcium, phosphorus, and vitamin D intakes are usually normal, but the condition can be prevented by the administration of calciferol. Carotene, which is present in large quantities in this type of feed, has been shown to have antivitamin D potency, but the existence of a further rachitogenic substance seems probable. The rachitogenic potency of this green feed varies widely according to the stage of growth and virtually disappears when flowering commences. Experimental overdosing with vitamin A causes a marked retardation of bone growth in calves. Such overdosing can occur when diets are supplemented with the vitamin and may produce clinical effects.

Exposure of animals to solar radiation is important in metabolism of vitamin D, with previtamin D 3 formed in the skin. Skin pigmentation—specifically, melanin— influences the amount of ultraviolet exposure needed to produce vitamin D 3. A longer time in sunlight is required for maximum previtamin D 3 formation in dark-skinned animals.

The importance of vitamin D to animals is now well recognized, and supplementation of the diet where necessary is usually performed by the livestock owner. Occasional outbreaks of vitamin D deficiency are experienced in intensive systems where animals are housed and in areas where specific local problems are encountered (e.g., rickets in sheep on green cereal pasture in New Zealand).

Animal Risk Factors

Most herbivores efficiently produce vitamin D 3 in the skin, and shorn sheep have higher concentrations of vitamin D 3 than do unshorn sheep.1 However, New World camels are particularly susceptible to vitamin D deficiency, likely as a result of errors in feed formulation resulting in vitamin D deficiency.4

Foals have lower serum vitamin D concentrations than do adult horses.10

PATHOGENESIS

Vitamin D is a complex of substances with antirachitic activity. Increasingly in human medicine, vitamin D is recognized as also having important roles in immune function and resistance to neoplasia and cardiovascular disease.1,12 The important components are as follows:

- Vitamin D 3 (cholecalciferol) is produced from its precursor 7-dehydrocholesterol in mammalian skin by natural irradiation with ultraviolet light (270 to 315 nm) over the course of 3 days.1
- Vitamin D 3 is present in certain plants, such as sun-cured hay, as a result of conversion of ergosterol to vitamin D 3 by ultraviolet light. Vitamin D 3 is present in and is produced by ultraviolet irradiation of plant sterols.
- Vitamin D 1 and D 3 occur naturally in the oils of some fish. Vitamin D produced in the skin or ingested with the diet and absorbed by the small intestine is transported to the liver. In the liver, 25-hydroxycholecalciferol is produced, which is then transported to the kidney, where at least two additional derivatives are formed by 1α-hydroxylase. One is 1,25-dihydroxycholecalciferol (DHCC), and the other is 24,25-DHCC. Under conditions of calcium need or calcium deprivation, the form predominantly produced by the kidney is 1,25-DHCC. At present, it seems likely that 1,25-DHCC is the metabolic form of vitamin D most active in eliciting intestinal calcium transport and absorption and is at least the closest known metabolite to the form of vitamin D functioning in bone mineralization. The metabolite also functions in regulating the absorption and metabolism of the phosphate ion and especially its loss from the kidney. A deficiency of the metabolite may occur in animals with renal disease, resulting in decreased absorption of calcium and phosphorus, decreased mineralization of bone, and excessive losses of the minerals through the kidney. A deficiency of vitamin D per se is governed in its importance by the calcium and phosphorus status of the animal.

Because of the necessity for the conversion of vitamin D to the active metabolites, there is a lag period of 2 to 4 days following the administration of the vitamin parenterally before a significant effect on calcium and phosphorus absorption can occur. The use of synthetic analogs of the active metabolites such as 1,25-dihydroxycholecalciferol (an analog of 1,25-DHCC) can increase the plasma concentration of calcium and phosphorus within 12 hours following administration and has been recommended for the control of parturient paresis in cattle.

Maternal Status

Maternal vitamin D status is important in determining neonatal plasma calcium concentration. There is a significant correlation between maternal and neonatal calf plasma
concentrations of 25-OH D₂, 25-OH D₃, 24,25-(OH)₂ D₂, 24,25-(OH)₂ D₃, and 25,26-(OH)₂ D₃. This indicates that the vitamin D metabolite status of the neonate is primarily dependent on the 25-OH D status of the dam. The maternal serum concentrations of calcium, phosphorus, and magnesium do not determine concentrations of these minerals found in the newborn call. The ability of the placenta to maintain elevated plasma calcium or phosphorus in the fetus is partially dependent on maternal 1,25-(OH)₂ D status. Parenteral cholecalciferol treatment of sows before parturition is an effective method of supplementing neonatal piglets of sows before parturition is an effective status. Parenteral cholecalciferol treatment of sows before parturition is an effective method of supplementing neonatal piglets with cholecalciferol via the sow's milk and its metabolite via placenta transport.

**Calcium:Phosphorus Ratio**

When the calcium:phosphorus ratio is wider than the optimum (1.1 to 2:1), vitamin D requirements for good calcium and phosphorus retention and bone mineralization are increased. A minor degree of vitamin D deficiency in an environment supplying an imbalance of calcium and phosphorus might well lead to disease, whereas the same degree of vitamin deficiency with a normal calcium and phosphorus intake could go unsuspected. For example, in growing pigs, vitamin D supplementation is not essential provided calcium and phosphorus intakes are rigidly controlled, but under practical circumstances, this may not be possible.

The minor functions of the vitamin include maintenance of efficiency of food utilization and a calorigenic action, with the metabolic rate being depressed when the vitamin is deficient. These actions are probably the basis for the reduced growth rate and productivity in vitamin D deficiency. Some evidence suggests that vitamin D may have a role in the immune system. Local production of 1,25-(OH)₂ D by monocytes may be important in immune function, particularly in the parturient dairy cow.

**Other Roles for Vitamin D**

Vitamin D is now recognized in humans to be important in immune function, particularly in the parturient dairy cow. Reproductive efficiency is also reduced, and the overall effect on the animal economy can be severe. The underlying mechanisms are unclear but could be related to the recently recognized pleiotropic effects of vitamin D (calcitriol).

In the late stages, lameness, which is most noticeable in the forelegs, is accompanied in young animals by bending of the long bones and enlargement of the joints. This latter stage of clinical rickets may occur simultaneously with cases of osteomalacia in adults. An adequate intake of vitamin D appears to be necessary for the maintenance of fertility in cattle, particularly if the phosphorus intake is low. In one study in dairy cattle, the first ovulation after parturition was advanced significantly in vitamin D-supplemented cows.

**CLINICAL PATHOLOGY**

**Serum Calcium and Phosphorus**

A pronounced hypophosphatemia occurs in the early stages and is followed some months later by a fall in serum calcium. Plasma alkaline phosphatase levels are usually elevated. The blood picture quickly returns to normal with treatment, often several months before the animal is clinically normal. Typical figures for beef cattle kept indoors are serum calcium 8.7 mg/dL (10.8 normal), 2.2 mmol/L (2.7 normal); serum inorganic phosphate 4.3 mg/dL (6.3 normal), 1.1 mmol/L (1.6 normal); and alkaline phosphatase 5.7 units (2.75 normal).

**Plasma Vitamin D**

The normal ranges of plasma concentrations of vitamin D and its metabolites in the farm animal species are now available and can be used to monitor the response of the administration of vitamin D parenterally or orally in sheep. The serum concentrations of vitamin D in the horse have been determined.

**Necropsy Findings**

The pathologic changes in young animals are those of rickets, whereas in older animals there is osteomalacia. In all ages, a variable amount of osteodystrophia fibrosa may develop, and distinction of the origin of these osteodystrophies based on only gross and microscopic examination is impractical. A review of management factors and a nutritional analysis of the feed are essential. The samples for confirmation of the diagnosis at necropsy are as per calcium deficiency.

**Differential Diagnosis**

A diagnosis of vitamin D deficiency depends on evidence of the probable occurrence of the deficiency and response of the animal when vitamin D is provided. Differentiation from clinically similar syndromes is discussed under the specific osteodystrophies.

**TREATMENT**

It is usual to administer vitamin D in the dose rates set out under “Control.” Affected animals should also receive adequate calcium and phosphorus in the diet.

**CONTROL**

**Supplementation**

The administration of supplementary vitamin D to animals by adding it to the diet or by injection is necessary only when exposure to sunlight or the provision of a natural ration containing adequate amounts of vitamin D is impractical.

A total daily intake of 7 to 12 IU/kg BW is optimal. Sun-dried hay is a good source, but green fodders are generally deficient in vitamin D. Fish liver oils are high in vitamin D, but they are subject to deterioration on storage, particularly with regard to vitamin A. They have the added disadvantages of losing their vitamin A and D content in pre-mixed feed, of destroying vitamin E in these feeds when they become rancid, and of seriously reducing the butterfat content of milk. Stable water-soluble vitamin A and D preparations do not suffer from these disadvantages. Irradiated dry yeast is probably a simpler and cheaper method of supplying vitamin D in mixed grain feeds.

Stable water-soluble preparations of vitamin D are now available and are commonly added to the rations of animals being fed concentrate rations. The classes of livestock that usually need dietary supplementation include the following:

- Calves raised indoors on milk replacers
- Pigs raised indoors on grain rations
- Beef cattle receiving poor-quality roughage during the winter months
- Cattle raised indoors for prolonged periods and not receiving sun-cured forage containing adequate levels of vitamin D—these include calves raised as herd replacements, yearling cattle fed concentrate rations, bulls in artificial insemination centers, and purebred bulls maintained indoors on farms.
- Feedlot lambs fed grain rations during the winter months or under totally covered confinement
- Young, rapidly growing horses raised indoors or outdoors on rations that may not contain adequate concentrations of calcium and phosphorus—this may be a problem in rapidly growing, well-muscled horses receiving a high level of grain.

Because there is limited storage of vitamin D in the body, compared with the storage of vitamin A, it is recommended that daily dietary supplementation be provided when possible for optimum effect.

**Injection**

In situations where dietary supplementation is not possible, the use of single IM injections of vitamin D₃ (calciferol) in oil will protect
ruminants for 3 to 6 months. A dose of 11,000 units/kg BW is recommended and should maintain an adequate vitamin D status for 3 to 6 months.

In mature nonpregnant sheep weighing about 50 kg, a single IM injection of 6000 IU/kg body weight produced concentrations of 25-hydroxyvitamin D, at adequate levels for 3 months. The parenteral administration of vitamin D results in both higher tissue and plasma levels of vitamin D than does oral administration, and IV administration produces higher plasma levels than does IM injection. The timing of the injection should be selected so that the vitamin D status of the ewe is adequate at the time of lambing. The vitamin D status of lambs can be increased by the parenteral administration of the vitamin to the pregnant ewe. Dosing pregnant ewes with 300,000 IU of vitamin D in a rapidly available form, approximately 2 months before lambing, provides a safe means of increasing the vitamin D status of the ewe and the newborn lambs by preventing seasonally low concentrations of 25-hydroxyvitamin D. In adult sheep, there is a wide margin of safety between the recommended requirement and the toxic oral dose, which provides ample scope for safe supplementation if such is desirable. In adult sheep given 20 times the recommended requirements for 16 weeks, there was no evidence of pathologic calcification. Oral dosing with 30 to 45 units/kg BW is adequate, provided treatment can be given daily. Massive oral doses can also be used to give long-term effects (e.g., a single dose of 2 million units is an effective preventive for 2 months in lambs). Excessive doses may cause toxicity, with signs of drowsiness, muscle weakness, fragility of bones, and calcification in the walls of blood vessels. The latter finding has been recorded in cattle receiving 10 million units/d and in unthrifty lambs receiving a single dose of 1 million units, although larger doses are tolerated by healthy lambs.

**VITAMIN D INTOXICATION**

Vitamin D intoxication has occurred in cattle, horses, alpacas and llamas, and pigs after the parenteral or oral administration of excessive quantities of the vitamin. It also occurs in horses, cattle, and sheep after ingestion of hay or silage containing large amounts of *Trisetum flavescens* (yellow oat grass).1,2

In cattle, large parenteral doses of vitamin D3 (15 to 17 million IU) result in prolonged hypercalcemia, hyperphosphatemia, and large increases in plasma concentrations of vitamin D3 and its metabolites. Clinical signs of toxicity occur within 2 to 3 weeks and include marked anorexia, loss of body weight, dyspnea, tachycardia, loud heart sounds, weakness, recumbency, torticollis, fever, and a high case-fatality rate. Pregnant cows 1 month before parturition are more susceptible than nonpregnant cows.

Hypercalcemia and hypervitaminosis D occurred in 17-day-old lambs being fed a milk replacer. The vitamin D content of the milk replacer was not excessive; there was no explanation for the abnormalities in the lamb, which recovered when the milk replacer was changed. Serum concentrations of calcium were high at 23.61 mg/dL and 23.09, respectively, in the two lambs.

Accidental vitamin D3 toxicity has occurred in horses fed a grain diet that supplied 12,000 to 13,000 IU/kg BW of vitamin D3 daily for 30 days, equivalent to about 1 million IU vitamin D3/kg of feed. Clinical findings included anorexia, stiffness, loss of body weight, polyuria, and polydipsia. There was also evidence of hypoesthesia, aciduria, soft tissue mineralization, and fractures of the ribs. Calcification of the endocardium and the walls of large blood vessels are characteristic.

Vitamin D intoxication occurs in pigs, usually as a result of errors in mixing of rations, and can result in polydipsia, polyuria, and weight loss.3 Severe toxicity in pigs occurs at a daily oral dose of 50,000 to 70,000 IU/kg BW. Signs include a sudden onset of anorexia, vomiting, diarrhea, dyspnea, apathy, aphony, emaciation, and death. Clinical signs are commonly observed within 2 days after consumption of the feed containing excessive vitamin D. At necropsy, hemorrhagic gastritis and mild interstitial pneumonia are commonly present. Arteriosclerosis with calcification of the heart base vessels may also be visible macroscopically in poisoned cattle. Osteoporosis with multiple fractures has been observed in subacute to chronic hypervitaminosis D in pigs. Histologically, there is widespread soft tissue mineralization, with a predilection for the lung and gastric mucosa, and elastin-rich tissue, such as blood vessels. Changes in bone vary with the duration of exposure to toxic levels of the vitamin.

Research notes development of vitamin D intoxication in New World camelid cria supplemented with vitamin supplements that provided doses of 4000 to 13,000 IU/kg per day over several days.4 The recommended dose of vitamin D to crias is a single parenteral dose of 1000 to 2000 IU/kg BW every 7 to 11 weeks.4 Clinical signs of intoxication in the supplemented crias included weakness and inappetence. There was azotemia, hypercalcemia, and hyperphosphatemia.4 Treatment was for acute renal failure.

Assay of the various metabolites of vitamin D in tissues is difficult. The diagnosis is therefore usually confirmed by correlating microscopic changes with a history of exposure to toxic levels of vitamin D.

**Samples for Confirmation of Diagnosis**

- **Toxicology**—500 g of suspect feed (ASSAY [Vit D])
- **Histology**—formalin-fixed lung, stomach/abomasum, proximal aorta, lung, bone (LM)

**REFERENCES**

**RICKETS**

**SYNOPSIS**

**Etiology** Deficiencies of any or combination of phosphorus and vitamin D, and less commonly calcium. Inherited forms are recognized in sheep and pigs.

**Epidemiology** Young, rapidly growing animals. No longer common. In calves on phosphorus-deficient diets (range or houset). In grazing lambs as a result of lack of solar irradiation. Rare in foals and pigs.

**Signs** Stiff gait and lameness, enlargement of ends of long bones, curvature of long bones, prolonged periods of recumbency. Delayed dentition.

**Clinical pathology** Elevated alkaline phosphatase; low serum calcium and phosphorus. Lack of density of bone radiographically.

**Necropsy findings** Abnormal bones and teeth. Bone shafts are soft, epiphyses enlarged. Ratio of bone ash to organic matter is decreased.

**Diagnostic confirmation** Histology of bone, especially epiphyses.

**Differential diagnosis list**

- Epiphysitis
- Congenital and acquired abnormalities
- Infectious synovitis

**Treatment** Vitamin D injections; calcium and phosphate orally.

**Control** Supplement deficient diets with calcium, phosphorus, and vitamin D.
Rickets is a disease of young growing animals caused by impaired mineralization of physeal and epiphyseal cartilage during endochondral ossification and of newly formed osteoid. Osteomalacia is the failure of calcification of osteoid in adult animals (i.e., after closure of the growth plate). The essential lesion is a failure of provisional calcification with persistence of hypertrophic cartilage and enlargement of the epiphyses of long bones and the costochondral junctions (so-called "rachitic rosary" of humans). The poorly mineralized bones are susceptible to fracture, compression, or both.

**ETIOLOGY**

Rickets is caused by an absolute or relative deficiency of any or a combination of calcium, phosphorus, or vitamin D in young growing animals. The effects of the deficiency are also exacerbated by a rapid growth rate.

An inherited form of rickets has been described in pigs. It is indistinguishable from rickets caused by nutritional inadequacy. The inherited form of the disease in Corriedale sheep is associated with increased expression of the gene for 25-hydroxyvitamin D3-24-hydroxylase, the enzyme responsible for catabolism of vitamin D.

**EPIDEMIOLOGY**

Clinical rickets is not as important economically as the subclinical stages of the various dietary deficiencies that produce it. The provision of diets adequate and properly balanced with respect to calcium and phosphorus and sufficient exposure to sunlight are mandatory in good livestock production. Rickets is no longer a common disease because these requirements are widely recognized, but the incidence can be high in extreme environments, including purely exploitative range grazing, intensive feeding in fattening units, and heavy dependence on lush grazing, especially in winter months.

Rickets is a disease of young, rapidly growing animals and occurs naturally under the following conditions.

**Calves**

Primary phosphorus deficiency in phosphorus-deficient range areas and vitamin D deficiency in calves housed for long periods are the common circumstances. Vitamin D deficiency is the most common form of rickets in cattle raised indoors for prolonged periods in Europe and North America. Grazing animals may also develop vitamin D deficiency rickets at latitudes where solar irradiation during winter is insufficient to promote adequate dermal photobiosynthesis of vitamin D3 from 7-dihydrocholesterol. Rickets has occurred in yearling steers in New Zealand wintered on swede (Brassica napus) crop deficient in phosphorus.

In young, rapidly growing cattle raised intensively indoors, a combined deficiency of calcium, phosphorus, and vitamin D can result in leg weakness characterized by stiffness, reluctance to move, and retarded growth. In some cases, rupture of the Achilles tendon and spontaneous fracture can occur. The Achilles tendon may rupture at the insertion of, or proximal to, the calcaneus.

**Lambs**

Lambs are less susceptible to primary phosphorus deficiency than cattle, but rickets does occur under the same conditions. Green cereal grazing and, to a lesser extent, pasturing on lush ryegrass during winter months may cause a high incidence of rickets in lambs; this is considered to be a secondary vitamin D deficiency. An outbreak of vitamin D–deficiency rickets involving 50% of lambs aged 6 to 12 months grazing new grass and rape occurred during the early winter months in Scotland. In the South Island of New Zealand, where winter levels of solar irradiation are low, rickets occurs in hoggets grazing green oats, or other green crops, which have been shown to contain high levels of rachitogenic carotenoids. The disease occurs in sheep flocks in northern England, likely for similar reasons to the disease occurring in New Zealand. A vitamin D–responsive rickets has occurred in twin lambs at 3 to 4 weeks of age.

**Pigs**

Rickets in young pigs occurs in intensive fattening units. The cause is assumed to be imbalances or mixing errors resulting in feed that contains excessive phosphate (high-cereal diets), or vitamin D and calcium deficiencies.

**Foals**

Rickets is uncommon in foals under natural conditions, although it has been produced experimentally.

**New World Camelids**

Llamas and alpacas are particularly susceptible to rickets secondary to vitamin D deficiency, a consequence of them evolving at high altitudes with consequent high exposure to solar radiation. Movement to lower altitudes, where the increased atmospheric depth reduces solar radiation, or indoor housing, reduces the opportunity for dermal production of vitamin D.

**CLINICAL FINDINGS**

The subclinical effects of the particular deficiency disease will be apparent in the group of animals affected and have been described in the earlier general section. Clinical rickets is characterized by the following:

- **Stiffness in the gait**
- **Enlargement of the limb joints, especially in the forelegs**
- **Enlargement of the costochondral junctions**
- **Long bones showing abnormal curvature, usually forward and outward at the carpus, in sheep and cattle**
- **Lameness and a tendency to lie down for long periods**

Outbreaks affecting 50% of a group of lambs have been described. Arching of the back and contraction, often to the point of virtual collapse, of the pelvis occur, and there is an increased tendency for bones to fracture.

**Eruption of the teeth is delayed** and irregular, and the teeth are poorly calcified, with pitting, grooving, and pigmentation. They are often badly aligned and wear rapidly and unevenly. These dental abnormalities, together with thickening and softness of the jaw bones, may make it impossible for severely affected calves and lambs to close their mouths. As a consequence, the tongue protrudes, and there is drooling of saliva and difficulty in feeding. In less severely affected animals, dental malocclusion may be a significant occurrence. Severe deformity of the chest may result in dyspnea and chronic ruminal tympany. In the final stages, the animal shows hypersensitivity, tetany, and recumbency and eventually dies of inanition.

**CLINICAL PATHOLOGY**

The plasma alkaline phosphatase activity is commonly elevated, but serum calcium and phosphorus levels depend on the causative factor. If phosphorus or vitamin D deficiencies are the cause, the serum phosphorus level will usually be below the normal lower limit of 3 mg/dL. The serum concentrations of 25-hydroxyvitamin D3 and 25-hydroxyvitamin D3 are markedly decreased in vitamin D–deficient rickets compared with the normal values of greater than 5 ng/mL. Serum vitamin D concentrations as low as 0.4 ng/mL have been reported in lambs with vitamin D–responsive rickets. Serum calcium levels will be low only in the final stages. In leg weakness of young, rapidly growing cattle, the serum concentration of 25-hydroxyvitamin D may be nondetectable.
and the serum levels of calcium and inorganic phosphorus may be low.

Radiographic examination of bones and joints is one of the most valuable aids in the detection of rickets. Rachitic bones have a characteristic lack of density compared with normal bones. The ends of long bones have a “woolly” or “moth-eaten” appearance and have a concave or flat, instead of the normal convex, contour. Surgical removal of a small piece of costochondral junction for histologic examination has been used extensively in experimental work and should be applicable in field diagnosis.

Necropsy findings

Apart from general poorness of condition, the necropsy findings are restricted to abnormal bones and teeth. The bone shafts are softer and larger in diameter, in part because of the subperiosteal deposition of osteoid tissue. The joints are enlarged, and on cutting, the epiphyseal cartilage can be seen to be thicker than usual. Histologic examination of the epiphysis is desirable for final diagnosis. In sheep, the best results are obtained from an examination of the distal cartilages of the metacarpal and metatarsal bones.

A valuable diagnostic aid is the ratio of ash to organic matter in the bone. Normally the ratio is 3 parts of ash to 2 of organic matter, but in rachitic bone this may be depressed to 1:2, or to 1:3 in extreme cases. A reduction below 45% of the bone weight as ash also suggests osteodystrophy. Because of the difficulty encountered in repeating the results of bone ash determinations, a standardized method has been devised in which the ash content of green bone is determined, using either the metacarpus or metatarsus of the animal. By comparing the ash content of green bone with that of normal bone, the ash content of the bone shafts can be calculated. This ratio is 3 parts of ash to 2 of organic matter in the bones. Normally, the ratio is 2.5:1.

Samples for Confirmation of Diagnosis

- Toxicology—long bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- Histology—formalin-fixed long bone (including growth plate) (LM)

Differential Diagnosis

Rickets occurs in young, rapidly growing animals and is characterized by stiffness of the gait and enlargement of the distal phalanges of the long bones, particularly noticeable on the metacarpus and metatarsus as circumscribed painful swellings. A history of a dietary deficiency of any of calcium, phosphorus, or vitamin D will support the clinical diagnosis. Radiographic evidence of widened and irregular physis suggests rickets. Copper deficiency in young cattle under 1 year of age can also result in clinical, radiographic, and pathologic findings similar to rickets. Clinically, there is an arched back, severe stiffness of gait, reluctance to move, and loss of weight. There are marked swellings of the distal aspects of metacarpus and metatarsus, and radiographically there is a widened zone of cartilage and lipping of the medial and lateral areas of the physeal plate. Copper concentration in plasma and liver are low, and there is usually dietary evidence of copper deficiency.

Epiphysitis occurs in rapidly growing yearling cattle raised and fed intensively under confinement. There is severe lameness, swelling of the distal physis, and radiographic and pathologic evidence of a necrotizing epiphysitis. The etiology is uncertain but thought to be related to the type of housing.

Congenital and acquired abnormalities of the bony skeletal system are frequent in newborn and rapidly growing foals. Rickets occurs, but only occasionally. “Epiphysitis” in young foals resembles rickets and is characterized by enlargements and abnormalities of the distal phalanges of the radius, tibia, third metacarpal, and metatarsal bones and the proximal extremity of the proximal phalanx. There may or may not be deviation of the limbs caused by uneven growth rates in various growth plates. The suggested causes include improper nutrition, faulty conformation and hoof growth, muscle imbalance, overweight, and compression of the growth plate. Recovery may occur spontaneously or require surgical correction.

Rickets in pigs is uncommon and the diagnosis can be difficult. The disease is usually suspected in young, rapidly growing pigs in which there is stiffness in the gait, walking on tip-toes, enlargements of the distal ends of long bones, and dietary evidence of a marginal deficiency of calcium or phosphorus. The radiographic and pathologic findings may suggest a rickets-like lesion.

Myocplasmal synovitis and arthritis clinically resemble rickets of pigs. There is a sudden onset of stiffness of gait, habitual recumbency, a decrease in feed consumption, and enlargements of the distal aspects of the long bones, which may or may not be painful; spontaneous recovery usually occurs in 10 to 14 days. The locomotor problems in young, growing pigs raised in confinement and with limited exercise must be considered in the differential diagnosis. In performance testing stations, up to 20% of boars may be affected with leg weakness.

Rickets in lambs must be differentiated from chlamydial and erysipelas arthritis, which are readily diagnosed at necropsy.

Treatment and Control

Recommendations for the treatment of the individual dietary deficiencies (calcium, phosphorus, and vitamin D) are presented under their respective headings. Lesser deformities recover with suitable treatment, but gross deformities usually persist. A general improvement in appetite and condition occurs quickly and is accompanied by a return to normal blood levels of phosphorus and alkaline phosphatase. The treatment of rickets in lambs with a vitamin A, vitamin D₃, calcium borogluconate solution containing magnesium and phosphorus parenterally and supplementation of the diet with bone meal and protein resulted in a dramatic response. Recumbent animals were walking within a few days.

Osteomalacia

Synopsis

Etiology Absolute or relative deficiency of any one or combination of calcium, phosphorus, and vitamin D in adult animals.

Epidemiology Primarily in cattle and sheep on phosphorus-deficient diets. In feedlot animals as a result of excessive phosphorus without complementary calcium and vitamin D.

Signs Reduced productivity, licking and chewing inanimate objects, stiff gait, moderate nonspecific lameness, shifting from leg to leg, cracking sounds while walking, arched back, lying down for long periods. “Milk lameness” in high-producing dairy cows on deficient diet.

Clinical pathology Increased alkaline phosphatase, decreased serum phosphorus levels. Decreased density of long bones radiographically.

Necropsy findings Decreased density of bones; erosions of articular cartilages.

Diagnostic confirmation Histology of bones.

Differential diagnosis list

- Chronic fluorosis
- Polyosynovitis and arthritis
- Spinal cord compression

Treatment As for calcium, phosphorus, and vitamin D deficiency.

Control Adequate supplementation of diet.
Osteomalacia is a disease of mature animals affecting bones in which endochondral ossification has been completed. The characteristic lesion is osteoporosis and the formation of excessive uncalcified matrix (osteoid). Lameness and pathologic fractures are the common clinical findings.

**ETIOLOGY**
In general, the etiology and occurrence of osteomalacia are the same as for rickets, except that the predisposing cause is not the increased requirement of growth but the drain of lactation, pregnancy, or both.

**EPIDEMIOLOGY**
Osteomalacia occurs in mature animals under the same conditions and in the same areas as rickets in young animals, but it is recorded less commonly. Its main occurrence is in cattle in areas seriously deficient in phosphorus. It occurs in goats. It is also recorded in sheep, again in association with hypophosphatemia. In pastured animals, osteomalacia is most common in cattle, and sheep raised in the same area are less severely affected. In feedlot animals, excessive phosphorus intake without complementary calcium and vitamin D is likely as a cause, especially if the animals are kept indoors. It also occurs in sows that recently weaned their pigs after a long lactation period (6 to 8 weeks) while on a diet deficient in calcium. A marginal deficiency of both phosphorus and vitamin D will exaggerate the condition. Intensively fed yearling cattle with inadequate mineral supplementation may be affected with spontaneous fractures of the vertebral bodies, pelvic bones, and long bones, leading to recumbency. Simply handling the animals through a chute for routine activities such as tuberculin testing may precipitate the fractures.

**PATHOGENESIS**
Increased resorption of bone mineral to supply the needs of pregnancy, lactation, and endogenous metabolism leads to osteoporosis and weakness and deformity of the bones. Large amounts of uncalcified osteoid are deposited around the diaphyses. Pathologic fractures are commonly precipitated by sudden exercise or handling of the animal during transportation. There is evolving understanding of the role of fibroblast growth factor 23 in this disease and other diseases (rickets) associated with abnormalities in calcium, phosphorus, or vitamin D metabolism.

**CLINICAL FINDINGS**
Ruminants
In the early stages, the signs are those of phosphorus deficiency, including lowered productivity and fertility and loss of condition. Licking and chewing of inanimate objects begins at this stage and may bring their attendant ills of oral, pharyngeal, and esophageal obstruction; traumatic reticuloperitonitis; lead poisoning; and botulism.

The signs specific to osteomalacia are those of a painful condition of the bones and joints and include a stiff gait; moderate lameness, often shifting from leg to leg; cracking sounds while walking; and an arched back. The hindlegs are most severely affected, and the hocks may be rotated inward. The animals are disinclined to move, lie down for long periods, and are unwilling to get up. The colloquial names “pegleg,” “creeps,” “stiffs,” “cripples,” and “bog lame” describe the syndrome aptly. The names “milkleg” and “milk lameness” are commonly applied to the condition when it occurs in heavily milking cows. Fractures of bones and separation of tendon attachments occur frequently, often without apparent precipitating stress. In extreme cases, deformities of bones occur; when the pelvis is affected, dystocia may result. Finally, weakness leads to permanent recumbency and death from starvation.

**Pigs**
Affected sows are usually found recumbent and unable to rise from lateral recumbency or from the dog-sitting position. The shaft of one femur or the neck of the femur is commonly fractured. The fracture usually occurs within a few days following weaning of the pigs. The placing of the sow with other adult pigs usually results in some fighting and increased exercise, which commonly precipitates the pathologic fractures.

**CLINICAL PATHOLOGY**
In general, the findings are the same as those for rickets, including increased serum alkaline phosphatase and decreased serum phosphorus levels. Radiographic examination of long bones shows decreased density of bone shadow.

**NECROPSY FINDINGS**
It can be difficult to discern any gross changes as the epiphyses are seldom enlarged, and the altered character of cancellous bone may not be macroscopically visible. Cortical bone may be somewhat thinned, and erosions of the articular cartilages have been recorded in cattle suffering from primary phosphorus deficiency. The parathyroid glands may be enlarged. Histologically, abnormal osteoid covers trabeculae, and a degree of fibrous tissue proliferation is often evident. Analysis reveals the bones to be lighter than normal with a low ratio of ash to organic matter.

**Samples for Confirmation of Diagnosis**
- **Toxicology**—long bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed bone, parathyroid (LM)

**DIFFERENTIAL DIAGNOSIS**
The occurrence of nonspecific lameness with pathologic fractures in mature animals should arouse suspicion of osteomalacia. There may be additional evidence of subnormal productivity and reproductive performance and dietary evidence of a recent deficiency of calcium, phosphorus, or vitamin D.

A similar osteoporotic disease of cattle in Japan has been ascribed to a dietary deficiency of magnesium. The cattle are on high-concentrate, low-roughage diets and have high serum calcium and alkaline phosphatase levels but a low serum magnesium level. The osteoporosis is observable at slaughter, and clinical signs observed are those of intercurrent disease, especially ketosis, milk fever, and hypomagnesemia. Reproductive and renal disorders occur concurrently.

In cattle it must be differentiated from chronic fluorosis in mature animals, but the typical motting and pitting of the teeth and the enlargements on the shafts of the long bones are characteristic. In some areas (e.g., northern Australia) where the water supply is obtained from deep subartesian wells, the two diseases may occur concurrently. Analysis of water supplies and foodstuffs for fluorine may be necessary in doubtful cases.

In sows, osteomalacia with or without pathologic fractures must be differentiated from spinal cord compression as a result of a vertebral body abscess and chronic arthritis resulting from erysipelas.

**TREATMENT AND CONTROL**
Recommendations for the treatment and control of the specific nutritional deficiencies have been described under their respective headings. Some weeks will elapse before improvement occurs, and deformities of the bones are likely to be permanent.

**REFERENCES**

**OSTEODYSTROPHIA FIBROSA**
Osteodystrophia fibrosa is similar in its pathogenesis to osteomalacia, but it differs in that soft, cellular, fibrous tissue is laid down as a result of the weakness of the bones instead of the specialized uncalcified osteoid tissue of osteomalacia. It occurs in horses, goats, and pigs. The disease occurs in large animals, principally equids, as a result of secondary nutritional hyperparathyroidism. Renal hyperparathyroidism, as is widely recognized in dogs, is rare to nonexistent in equids.

**ETIOLOGY**
A secondary calcium deficiency resulting from excessive phosphorus feeding is the
common cause in horses and probably also in pigs. The disease also occurs in horses grazing tropical or subtropical pastures containing buffel, pangola, setaria, kikuyu, green panic, guinea, signal, and purple pigeon grasses. These tropical grasses contain oxalate, which interferes with mineral utilization by horses forming calcium oxalate, which renders the calcium unavailable for intestinal absorption. Grasses with more than 0.5% oxalate or calcium:oxalate ratios of less than 0.5 result in a negative calcium balance and are capable of inducing hypocalcemia in horses. The disease can be readily produced in horses on diets with a ratio of calcium:phosphorus of 1:2.9 or greater, irrespective of the total calcium intake. Calcium:phosphorus ratios of 1:0.9 to 1:1.4 have been shown to be preventive and curative. With a very low calcium intake of 2 to 3 g/d and a calcium:phosphorus ratio of 1:13, the disease may occur within 5 months. With a normal calcium intake of 26 g/d and a calcium:phosphorus ratio of 1:5, obvious signs appear in about 1 year, but shifting lameness may appear as early as 3 months.

The disease is reproducible in pigs on similar diets to those just described and also on diets low in both calcium and phosphorus. The optimum calcium:phosphorus ratio is 1.2:1, and the intake for pigs should be within the range of 0.6% to 1.2% of the diet.

**EPIDEMIOLOGY**

Osteodystrophia fibrosa is principally a disease of horses and other Equidae and to a lesser extent of pigs. It occurs in goats. Previously, among horses, those engaged in heavy city work and in racing were more likely to be affected because of the tendency to maintain these animals on unbalanced diets. Widespread adoption of use of commercial diets and recognition of the importance of correct mineral nutrition has likely decreased the importance of this disease in these animals. The disease in developed countries is now restricted to equids fed inadequate or imbalanced diets. The major occurrence is in horses fed a diet high in phosphorus and low in calcium. Such diets include cereal hays combined with heavy grain or bran feeding. Legume hays, because of their high calcium content, are preventive.

The disease may reach endemic proportions in army horses moved into new territories, whereas local horses, more used to the diet, suffer little. Although horses may be affected at any age after weaning, it is the 2-to-7-year age group that suffers most, probably because they are the group most likely to be exposed to the rations that predispose to the disease.

A novel occurrence has been recorded of an endemic form of the disease affecting large numbers of horses at pasture. The dietary intake of calcium and phosphorus and their proportions were normal. The occurrence was thought to be caused by the continuous ingestion of oxalate in specific grasses: Cenchrus ciliaris, Panicum maximum var. trichoglochne, Setaria anceps, Brachiaria mutica, and Pennisetum clandestinum.

**PATHOGENESIS**

Defective mineralization of bones follows the imbalance of calcium and phosphorus in the diet, and a fibrous dysplasia occurs. This may be in response to the weakness of the bones, or it may be more precisely a response to hyperparathyroidism stimulated by the excessive intake of phosphorus. The weakness of the bones predisposes to fractures and separation of muscular and tendinous attachments. Articular erosions occur commonly, and displacement of the bone marrow may cause the development of anemia.

**CLINICAL FINDINGS**

Horse

As in most osteodystrophies, the major losses are probably in the early stages before clinical signs appear or on diets where the aberration is marginal. In horses, a shifting lameness is characteristic of this stage of the disease, and arching of the back may sometimes occur. The horse is lame, but only mildly so, and in many cases, no physical deformity can be found by which the seat of lameness can be localized. These signs probably result from relaxation of tendon and ligaments and appear in different limbs at different times. Articular erosions may contribute to the lameness. In more advanced cases, severe injuries, including fracture and visible sprains of tendons, may occur, but these are not specific to osteodystrophia fibrosa, although their incidence is higher in affected than in normal horses. Fracture of the lumbar vertebrae while racing has been known to occur in affected horses.

The more classical picture of the disease has largely disappeared because cases are seldom permitted to progress to this advanced stage. Local swelling of the lower and alveolar margins of the mandible is followed by soft, symmetric enlargement of the facial bones, which may become swollen so that they interfere with respiration. Initially these bony swellings are firm and pyramidal and commence just above and anterior to the facial crests. The lesions are bilaterally thickened and distorted. The fleshy mucosa covering these bony swellings is thinned and abnormally oriented bony trabeculae. The parathyroid glands are enlarged. It must be remembered that osteodystrophia fibrosa is a lesion, not a disease. The pathway to this lesion usually involves a dietary imbalance in calcium and phosphorus, but the kidneys should also be examined to rule out the possibility of renal secondary hyperparathyroidism.

**NOCROPSY FINDINGS**

The entire skeleton is abnormal in this severe form of metabolic bone disease, but the change is most notable in the mandibular, maxillary, and nasal bones, which may appear thickened and distorted. The fleshy tissue that replaces normal cancellous bone in these sites is also present in the metaphyses of the long bones. Microscopically, there is proliferation of fibrous tissue and markedly increased osteoclast activity along thinned and abnormally oriented bony trabeculae. The parathyroid glands are enlarged.

**CLINICAL PATHOLOGY**

There are no significant changes in blood chemistry in horses affected with severe osteodystrophia fibrosa. However, the serum calcium level will tend to be lower than normal, the serum inorganic phosphorus higher than normal, and the alkaline phosphatase activity higher than normal. The levels of diagnostic alkaline phosphatase have not been determined. Affected horses may be unable to return their serum calcium levels to normal following the infusion of a calcium salt. Radiographic examination reveals increased translucency of bones, especially of the mandibles.

**Samples for Confirmation of Diagnosis**

- **Toxicology**—bone (ASSAY [ash]); 500 g feed (ASSAY [Ca] [P] [Vit D])
- **Histology**—formalin-fixed bone, parathyroid gland, kidney (LM)
**DIFFERENTIAL DIAGNOSIS**

In the early stages, the diagnosis may be difficult because of the common occurrence of traumatic injuries to horses’ legs. A high incidence of lameness in a group of horses warrants examination of the ration and determination of their calcium and phosphorus status. An identical clinical picture has been described in a mare with an adenoma of the parathyroid gland. Inherited multiple exostosis has been described in the horse.

In pigs, osteodystrophia can be the result of hypovitaminosis A and experimentally as a result of manganese deficiency.

**TREATMENT AND CONTROL**

A ration adequately balanced with regard to calcium and phosphorus (calcium: phosphorus should be in the vicinity of 1:1 and not wider than 1:1.4) is preventive in horses, and affected animals can only be treated by correcting the existing imbalance. Even severe lesions may disappear in time with proper treatment. Cereal hay may be supplemented with alfalfa or clover hay, or finely ground limestone (30 g daily) should be fed. Dicalcium phosphate and bone meal are not as efficient because of their additional content of phosphorus.

**REFERENCES**

**“BOWIE” OR “BENTLEG” IN LAMBS**

Bowie is a disease of lambs of unknown etiology characterized by carpus valgus, and less commonly carpus varus, resulting in a lateral displacement of the carpus and medial displacement of the hooves. The lesions differ from those of rickets. It has been observed only on unimproved range pasture in New Zealand and in South Africa. The cause is unknown, although phosphorus deficiency has been suggested. A similar syndrome has been produced by the feeding of wild parsnip (*Trichocereus glaucifolius*) and, experimentally, by the feeding of a diet low in both calcium and phosphorus. There is no clear genetic component to the disease in South Africa.

Improvement of the pasture by top dressing with superphosphate and sowing improved grasses is usually followed by disappearance of the disease. Only suckling lambs are affected, and cases occur only in the spring at a time when rickets does not occur. Up to 40% of a group of lambs can be affected without breed differences in incidence. Signs of the disease can be evident at 3 to 4 weeks of age.

The disease has also been reported from South Africa, where it occurs primarily in ram lambs and develops from as early as 3 months up to 1 year of age. There is gradual bending of the forelimbs, with the hooves turned inward and the carpal joints turned outward. Animals of the South African Mutton Merino breed had significantly higher plasma phosphorus concentrations than those of the Merino and Dohne Merino breeds. The plasma calcium:phosphorus ratio was lower in affected lambs and their ewes, and this converse ratio is thought to result in an induced plasma ionized calcium deficiency leading to improper calcification of bone.

Some tenderness of the feet and lateral curvature at the knees can be seen as early as 2 to 3 weeks of age, and marked deformity is present at 6 to 8 weeks, with maximum severity at weaning. The forelimbs are more commonly affected than the hindlimbs. Carpus varus occurs in rare cases. The sides of the feet become badly worn, and the lateral aspects of the lower parts of the limbs can be injured and be accompanied by lameness. The lambs grow well at first, but by the time of weaning, affected lambs are in poor condition because of their inability to move about and feed properly. A rather similar syndrome has been observed in young Saanen bucks, but the condition showed a tendency to recover spontaneously.

At necropsy lesions are restricted to the radius and metacarpus with medial collapse of the distal radial epiphysis and consequent carpus valgus. There is often excessive synovial fluid in the carpal joints; in the later stages, there are articular erosions. Increased deposition of osteoid is not observed. Supplementation of the diet with phosphorus or improvement of the pasture seems to reduce the incidence of the disease. Dosing with vitamin D or providing mineral mixtures containing all trace elements is ineffective.

**DEGENERATIVE JOINT DISEASE AND OSTEOARTHRITIS**

Degenerative joint disease in food animals describes severe, progressive, nonseptic arthropathy in growing animals that is the result of one or more processes that lead to damage to articular cartilage and consequent osteoarthritis. The insult can be to cartilage or underlying bone as a result of metabolic, nutritional, congenital, or traumatic causes but can be difficult to identify because the insult to tissues causing the disease usually occurs weeks to months before clinical signs of disease. Degenerative joint disease can affect almost any diarthrodial joint. The most severe disease occurs when affected joints are loaded with weight. The disease is well documented and researched in racehorses in which it is the end result of damage to articular cartilage. According to some studies, greater than 90% of steers are affected by osteoarthritis, and it is an important cause of infertility in beef bulls. The disease is most often seen in the stifle joint, where the predilection sites are the medial and lateral condyles and the patellar groove. Most lesions are bilateral.

Degenerative arthropathy occurs in cattle of all breeds but reaches its highest incidence as a sporadic disease of young beef bulls. The disease has been identified as hip dysplasia because of the preexisting shallow contour of the acetabulum. It is considered to be inherited as a recessive characteristic and exacerbated by rapid weight gain in young animals. The occurrence of the condition in these animals is usually associated with rearing on pasture and nurse cows, housing for long periods, provision of a ration high in cereal grains and byproducts (i.e., a high phosphorus: calcium ratio), and possibly with an inherited straight conformation of the hindlegs. Although the disease occurs in all beef breeds, there is a strong familial tendency that appears to be directly related to the rate of body-weight gain and the straightness of the hindleg. If the potential for rapid weight gain is being realized in animals being force fed, the rate of occurrence appears to be dependent on their breeding, and animals in the same herd that are allowed to run at pasture under natural conditions are either not affected or are affected at a much later age. Thus animals in a susceptible herd can show signs as early as 6 months of age if they are heavily hand-fed and raised on dairy cow foster mothers. In the same herd, signs do not appear until 1 to 2 years of age if supplementary feeding is not introduced until weaning and not until 4 years if there is no significant additional feeding.

Clinically there is a gradual onset of lameness in one or both hindlegs. The disease progresses, with the lameness becoming more severe over a period of 6 to 12 months. In some animals, there is a marked sudden change for the worse, usually related to violent muscular movements, as in breeding or fighting. In severely affected animals, the affected limb is virtually useless; on movement, distinct crepitus can often be felt and heard over the affected joints. This can be accomplished by rocking the animal from side to side or having it walk while holding the hands over the hip joints.

An additional method of examination is to place the hand in the rectum close to the hip joint while the animal is moved. Passive movement of the limb may also elicit crepitus or louder clinking or clicking sounds. The hip joints are always most severely affected, but in advanced cases, there may be moderate involvement of the stifles and minimal lesions in other joints. Affected animals lie down most of the time and are reluctant to
rise and to walk. The joints are not swollen, but in advanced cases, local atrophy of muscles may be so marked that the joints appear to be enlarged. There is a recorded occurrence in which the lesions were confined mainly to the front fetlocks.

Radiographic examination can provide confirmatory or diagnostic evidence but is restricted to facilities with equipment suited to these examinations.

At necropsy, the most obvious finding is extensive erosion of the articular surfaces, often penetrating to the cancellous bone, and disappearance of the normal contours of the head of the femur or the epiphyses in the stifle joint. The synovial cavity is distended, with an increased volume of brownish, turbid fluid; the joint capsule is much thickened and often contains calcified plaques. Multiple small exostoses are present on the periarticular surfaces. When the stifle is involved, the cartilaginous menisci, particularly the medial one, are very much reduced in size and may be completely absent. In cattle with severe degenerative changes in the coxo-femoral joint, an acetabular osseous bulla may be present at the cranial margin of the obturator foramen. Adequate calcium, phosphorus, and vitamin D intake and a correct calcium:phosphorus ratio in the ration should be ensured. Supplementation of the ration with copper at the rate of 15 mg/kg has also been recommended for the control of a similar disease.

Degenerative joint disease of cattle is recorded on an enzootic scale in Chile and is thought to be attributable to gross nutritional deficiency. The hip and tarsal joints are the only ones affected, and clinical signs appear when animals are 8 to 12 months old. There is gross lameness and progressive emaciation. An inherited osteoarthritis is described under that heading. Sporadic cases of degenerative arthropathy, with similar signs and lesions, occur in heavy-producing, aged dairy cows and are thought to be caused by long-continued negative calcium balance. Rare cases also occur in aged beef cows but are thought to be associated with an inherited predisposition. In both instances the lesions are commonly restricted to the stifle joints.

Degenerative arthropathy of the distal interphalangeal joints and sesamoid bones occurs in calves (Fig. 15-14). Affected animals have moderate to severe lameness of one or both forelimbs but no discernible distension of the joint. Treatment is palliative, involving administration of NSAIDs (meloxicam or phenylbutazone, where permitted by regulatory authorities) or surgery. Osteoarthritis occurs in the stifle joint of dairy breed bulls. Seventy-two percent (39/54) of stifle joints and 85% (23/27) of dairy bulls 31 to 60 months of age had at least one gross lesion, and 94% of the lesions were localized to the distal end of the femur, with the patellar groove and the lateral trochlear ridge being predilection sites.

Fig. 15-14 Degenerative joint disease (arrow) affecting P2 to P3 of a calf. (Reproduced with permission.)

Osteoarthritis of one or both temporomandibular joints occurs in ~1.3% of Soay sheep on the island of St. Kilda, being more common in older ewes. Osteoarthritis also occurs in the elbows of sheep. It can be bilateral, in which case the sheep have a characteristic stance with both hindfeet placed more cranially, under the abdomen, apparently in an effort to reduce weight-bearing by the forelegs. There is no definitive treatment.

MANGANESE DEFICIENCY
A dietary deficiency of manganese (Mn) can cause skeletal deformities, both congenitally and after birth, and infertility.

ETIOLOGY
A primary deficiency occurs endemically in some areas because of a geological deficiency of manganese in the local rock formations. Apart from a primary dietary deficiency of manganese, the existence of factors depressing the availability of ingested manganese is suspected. An excess of calcium and/or phosphorus in the diet increases the requirements of manganese in the diet of calves and is considered to reduce the availability of dietary manganese to cattle generally.

Congenital chondrodystrophy in calves has been associated with a manganese deficiency, and there are outbreaks of congenital skeletal defects in calves suspected to be attributable to manganese deficiency.

EPIDEMIOLOGY
Soils containing less than 3 mg/kg of manganese are unlikely to be able to support normal fertility in cattle. In areas where manganese-responsive infertility occurs, soils on farms with infertility problems have contained less than 3 mg/kg of manganese, whereas soils on neighboring farms with no infertility problems have had levels of more than 9 mg/kg. A secondary soil deficiency is thought to occur, and one of the factors suspected of reducing the availability of manganese in the soil to plants is high alkalinity.
Nutritional Diseases Affecting the Musculoskeletal System

**CLINICAL FINDINGS**

In cattle, the common syndromes in confirmed or suspected manganese deficiency are infertility, stillbirth, perinatal loss, calves with congenital limb deformities, and calves that manifest poor growth, dry coat, and loss of coat color.\(^2\) The deformities include knuckling over at the fetlocks, enlarged joints, and, possibly, twisting of the legs. The bones of affected lambs are shorter and weaker than normal, and there are signs of joint pain, hopping gait, and reluctance to move.

Heifers fed a low-manganese diet (16 mg Mn per kg DM of diet) during pregnancy had impaired fetal growth and development evident as lower birth weight than calves from heifers fed 50 mg of Mn per kg DM, superior brachygnathism, unsteadiness, disproportionate dwarfism, and swollen joints.\(^4\) A severe congenital chondrodystrophy in Charolais calves occurred on one farm. The limbs were shortened and the joints enlarged. The pregnant cows were fed on apple pulp and corn silage, both of which were low in manganese.

An outbreak of congenital skeletal malformations in Holstein calves was characterized clinically by small birth weights (average 15 kg). Abnormalities included joint laxity, doming of the foreheads, superior brachygnathia, and a dwarfishlike appearance as a result of the short length of the long bones. The features of the head were similar to those of the wildebeest. The majority of affected calves were dyspneic at birth, and snorting of the wildebeest. The majority of affected calves were dyspneic at birth, and snorting and grunting respiratory sounds were common. Affected calves failed to thrive, and most were culled because of poor performance.

A manganese-responsive infertility has been described in ewes and is well known in cattle. In cattle, it is manifested by slowness to exhibit estrus and failure to conceive, often accompanied by subnormal size of one or both ovaries. Subestrus and weak estrus have also been observed.

Functional infertility was once thought to occur in cattle on diets with calcium-to-phosphorus ratios outside the range of 1:2 to 2:1. This was not upheld on investigation but might have been correct if high calcium-to-phosphorus intakes directly reduced manganese (or copper or iodine) availability in diets marginally deficient in one or other of these elements.

In pigs, experimental diets low in manganese cause reduction in skeletal growth; muscle weakness; obesity; irregular, diminished, or absent estrus; agalactia; and resorption of fetuses or the birth of stillborn pigs. Leg weakness, bowing of the front legs, and shortening of bones also occur.

**PATHOGENESIS**

Manganese plays an active role in bone-matrix formation and in the synthesis of chondroitin sulfate, which is responsible for maintaining the rigidity of connective tissue. In manganese deficiency, these are affected deleteriously, and skeletal abnormalities result. Only 1% of manganese is absorbed from the diet, and the liver removes most of it, leaving very low blood levels of the element.

**Necropsy Findings**

In congenital chondrodystrophy in calves, the limbs are shortened, and all the joints are enlarged. Histologically, there is poor cartilage maturation with excessive amounts of rarefied cartilage matrix. The major histologic abnormality in the physes is disorderly development of the zones of cartilage hypertrophy, with reduced number and irregular arrangement of hypertrophic chondrocytes; similar but less severe changes are present in the zones of cartilage proliferation.\(^1\) There are degenerative changes in the chondrocytes and severe reduction in the mucopolysaccharide content of all body hyaline cartilage.

**Treatment and Control**

The NRC estimated the maintenance requirement (0.002 of available Mn/kg BW) of dairy cows from dietary concentrations of Mn reported to cause Mn deficiency in cattle. Based on NRC of 2001 equations, the maintenance requirement for Mn...
represents 82% of the total Mn requirement for a nonlactating, late-gestation cow and 53% for a cow producing 40 kg/d of milk. Fecal loss of endogenous Mn is assumed to comprise the entire maintenance requirement. Assuming typical dry matter intake (DMI), a diet with approximately 14 mg Mn/kg DM will meet the requirement for a 700-kg nonlactating cow during the last month of lactation. Recent research has determined that Mn intake had to equal 580 mg/d to meet the metabolic fecal Mn requirement. The corresponding dietary concentrations, assuming DMIs of 21 and 12 kg/d for lactating and dry cows, respectively, were 28 and 49 mg/kg DM. These concentrations are approximately 1.6 and 2.7 times higher than those needed to meet the Mn requirements for lactating and dry cows, respectively, as calculated using the 2001 NRC dairy nutrient requirements model. Supplementation of 50 mg of Mn/kg of DM to the control diet of heifers was sufficient to overcome any signs of Mn deficiency in calves; the control diet contained ~17 mg Mn per kg DM. 

For pigs, the recommended dietary intakes are 24 to 57 mg manganese per 45 kg BW. Expressed as a proportion of food intake, the recommended dietary level is 40 mg/kg DM in feed. The manganese requirements for gestation and lactation are 20 ppm of the diet.

Supplementation with high levels of manganese to cattle fed a copper-deficient diet can further impair copper absorption, with consequent reductions in the growth and health of cattle.

BIOTIN (VITAMIN H) DEFICIENCY (HYPOBIOTINOSIS)

Biotin, or vitamin H, has several important biochemical functions. It is a cofactor in several enzyme systems involved in carboxylation and transcarboxylation reactions and consequently has a significant effect on carbohydrate metabolism, fatty acid synthesis, amino acid deamination, purine synthesis, and nucleic acid metabolism. Biotin is found in almost all plant and animal materials and, being required in very small quantities, is unlikely to be deficient in diets under natural conditions, especially because microbial synthesis occurs in the alimentary tract.

Cattle
Biotin is now considered a significant factor in lameness of cattle. It is possible that biotin improves the quality of claw horn, which encourages the replacement of defective horn, improves healing, and makes it less likely for sole lesions to develop from laminitis in its early stages. The administration of biotin at 40 mg per day for 50 days to dairy cows with uncomplicated sole ulcers resulted in significant improvement in histologic horn quality of the newly formed epidermis covering the sole ulcer. Biotin supplementation at 20 mg/d for the differentiation of epidermal cells, which are required for normal production of keratin and hoof horn tissue. Biotin also acts as a cofactor in carboxylase enzymes and is an important factor in both gluconeogenesis and fatty acid synthesis. Significant differences in the fatty acid profile of horn tissue of cattle with claw lesions have been observed. Biotin supplementation reduces clinical white-line disease, reduces horn lesions, and improves horn quality by strengthening the intercellular cementing material between keratinocytes. Improved hoof integrity in intensively managed dairy cows has occurred following biotin supplementation. However, a long period of supplementation is required before the effect of the vitamin on hoof health care is expressed. In addition, there can be improved milk production, milk composition, and cow fertility with biotin supplementation, although this finding is not consistent across studies.

Biotin is synthesized in the rumen, and absolute biotin deficiency has not been recognized. However, ruminal synthesis of biotin may be compromised by acidic conditions in the rumen, which may increase the need for supplementation of biotin in the diet of high-producing dairy cows. In the dairy cow in the periparturient period and early lactation, the levels of biotin may decrease. A decrease in plasma biotin levels of dairy cows at 25 days in milk (DIM) has been noted, returning to constant levels from 100 DIM until the end of lactation. Feeding supplemental biotin at 20 g/d during the last 16 days postpartum and at 30 g/d from calving through to 70 days postpartum elevated concentrations of plasma and milk compared with cows unsupplemented with biotin. Supplemental biotin also elevated plasma glucose and lowered nonesterified fatty acids, which indicates that supplemental biotin is involved in hepatic gluconeogenesis. The triacylglycerol concentration in liver tended to decrease at a faster rate within 2 days after parturition.

Supplementation of young, extensively managed cattle with 12.5 g of diluted powdered biotin, or a control treatment, for 40 consecutive days revealed an effect of biotin to increase average hoof growth of 11.3 +/- 0.72 mm in supplemented cattle versus 7.2 +/- 0.78 mm over the 40 days. There was a positive effect of biotin supplementation on the growth of the angle and length of the dorsal hoof wall and the hoof sole length, and on resistance to wearing in young, extensively managed cattle. The supplementation of Holstein cows in the Atherton Tablelands in Australia with biotin at 20 mg/head per day resulted in improved locomotion scores compared with unsupplemented cows. In the wet summer period, the number of lame cows observed by the farmer was significantly fewer during the rainy period for the biotin-supplemented herds, and animals in the herd required fewer antibiotic treatments than unsupplemented herds. Most hoof lesions were most commonly observed in the outer claws of the hindlimb.

In a randomized control field trial on five commercial dairy farms in Gloucestershire, southwest United Kingdom, the effect of parity and duration of supplementation with oral biotin at 20 mg/d on white-line disease was studied over a period of 18 months. The incidence of white-line disease increased with increasing parity independent of biotin supplementation from 2 cases per 100 cow-years in primiparous cows to 15.5 cases per 100 cow-years in multiparous cows, but up to 47.7 cases per 100 cow-years for cows in parities = 5. Supplementation with biotin reduced white-line disease lameness by 45% in multiparous cows down to 8.5 cases per 100 cow-years, whereas the effect of biotin supplementation in primiparous cows was not significant. A supplementation of length of at least 6 months was required to reduce the risk of white-line lameness in multiparous cows. The overall incidence rate of lameness (per 100 cows per year) was 68.9, with a range of 31.6 to 111.5 per farm. The incidence rates of the four most frequently reported causes of lameness were sole ulcer, 13.8; white-line separation, 12.7; digital dermatitis, 12.0; and interdigital necrobacillosis, 7.1 per 100 cows per year. The incidence of lameness was highly variable between farms. However, when the data from all farms were pooled, the risk of lameness caused by white-line separation in cattle supplemented with biotin was approximately 50%. Approximately 130 days of biotin supplementation is required before a significant difference in white-line lesion lameness occurs.

A controlled 14-month field trial evaluated the effect of biotin supplementation on hoof lesions, milk production, and reproductive performance of dairy cows housed in the same free-stall facility with the same environment, base diet, and management. Supplemented cows received 20 mg/d by computer feeder. The feet of a select number of cows were trimmed three times at 6-month intervals, and hoof health was evaluated. At the final hoof trimming, the incidence of sole hemorrhages was significantly higher in the control group (50%) compared with the supplemented group (24%). No cases of lameness occurred. Milk production and fat yield increased in all parities, and fertility was improved in first-calf heifers.
did not affect the tensile strength of the white line. Vertical fissures, or sand cracks, are vertical cracks of the hoof that may extend across the coronary band and continue to the bearing surface of the dorsal wall of the claw. Sand cracks are common in beef cattle in western Canada. One survey, 37.5% of beef cows were affected with one or more cracks. Supplementary dietary biotin at 10 mg/head per day significantly increased serum levels of biotin and increased claw hardness compared with unsupplemented cows. After 18 months, 15% of the biotin-supplemented cows had vertical fissures compared with 35% in the unsupplemented cows.

**Sheep**

There is evidence from a small number of studies that biotin supplementation of the diets of sheep improves hoof health.

**Pigs**

The principal source of biotin for the pig is the feed it receives, and feeds vary greatly in their biotin content and in the biological availability of that biotin. Diets based on cereals with a low available biotin content may provide insufficient dietary biotin for the maintenance of hoof horn integrity in pigs. The biotin content in basal diets fed to pigs has varied from 29 to 15 µg/kg available biotin, and supplementation of these diets has resulted in improvements in litter size. Continuous feeding of sulfonamides or antibiotics may induce a deficiency. An antivitamin to biotin (avidin) occurs in egg white, and biotin deficiency can be produced experimentally by feeding large quantities of uncooked egg white.

In pigs, experimental biotin deficiency is manifested by alopecia, dermatitis, and painful cracking of the soles and the walls of the hooves. Naturally occurring outbreaks of lameness in gilts and sows associated with lesions of the soles and the walls of the hooves, which responded to biotin supplementation, have now been well described. The severe lameness and long course of convalescence have been responsible for a high rate of culling in breeding animals. In gilts fed a basal diet with a low level of biotin (32 µg available biotin/kg) from 25 kg live weight to 170 days of age, there were no significant differences in the number of lesions and claws affected compared with gilts fed a biotin-supplemented diet (350 µg available biotin/kg). However, between 170 days of age and the first weaning, the incidence of hoof lesions increased markedly. Over the next four litters, the incidence of lesions increased with the age of the sow. The predominant lesions in the foot were cracks, which occurred mainly in two associated regions: the heel/toe junction and the heel and the sidewall and adjacent white-line region of the toe. Supplementation of the diet of breeding sows with biotin at an early stage of development makes a significant contribution to the maintenance of horn integrity. Affected animals become progressively lame after being on a biotin-deficient ration for several months. Arching of the back and a hunched stance with the hindlegs positioned forward occurs initially. This posture has been described as a “kangaroo-sitting” posture. The foot pads become softer and the hoof horn less resilient. The feet are painful, and some sows will not stand for breeding. Deep fissures at the wall–sole junction may extend upward beneath the wall horn, and gaping cracks may separate the toe and heel volar surfaces. The foot pads initially show excessive wear; later, longitudinal painful cracks develop. In well-developed cases, the foot pads appear enlarged, and the cracks are obvious and covered by necrotic debris. The foot pads of the hindfeet are usually more severely affected than those of the forefeet, and the lateral digit is more frequently affected. The dewclaws also are affected by cracks and the accumulation of necrotic tissue.

Skin lesions also develop in affected gilts and sows. There is gradual alopecia, particularly over the back, the base of the tail, and the hindquarters. The hairs are more bristly than normal and break easily. The alopecia is accompanied by a dryness of the skin. As the lesions of the feet and skin develop there is a marked drop in the serum biotin concentrations, which is considered as a sensitive index of biotin deficiency. Adequate biotin status may be indicated by serum biotin levels (ng/L) greater than 700; marginal, 600 to 700; inadequate, 400 to 600; and deficient, below 400. Compression and hardness tests made on external hoof have also been used as an indirect measure of biotin adequacy in pigs. The tests indicate that significant improvements in the strength and hardness of pig hoof horn are produced by biotin. Supplementation of the diet with biotin does not affect either horn growth or wear rates. Biotin supplementation does affect the structure of the coronary epidermis; there is an increase in the density of the horn tubules in the stratum medium, the horny squames in the stratum medium are more tightly packed, and the tubules are more clearly defined.

Reproductive performance of sows is also influenced by their biotin status. Supplementation of the diet with biotin may increase litter size, increase the number of pigs weaned, decrease the mean interval in days from weaning to service, and improve conception rate. Over a period of four parities, piglet production increased by 1.42 pigs/sow year.

**Biotin Requirements**

**Pigs**

The daily requirements of biotin for pigs have not been well defined, but certain amounts have been associated with an absence of lameness and improved reproductive performance. Basic diets for gilts contain 35 to 50 µg/kg, and the addition of 350 to 500 µg/kg is recommended. This provides a daily intake of 4.0 to 5.0 mg/sow per day. The response to dietary supplementation may take several months; therefore, supplementation should begin at weaning.

**HYENA DISEASE OF CATTLE**

Hyena disease of cattle occurs worldwide and is characterized clinically by a lateral body appearance similar to the hyena. The...
cause is unknown for some cases, but sustained excessive intake of vitamin A and vitamin D₃ in young calves appears to be the most likely cause of hyena disease by suppressing differentiation and proliferation in chondrocytes and osteoblasts. This effect is clinically detectable because of premature closure of the physs of long bones. A small number of cases may be a result of systemic viral disease of young calves.

In some naturally occurring cases in yearlings from one large dairy herd, approximately 1% of calves were affected annually. Affected calves had received vitamins A and D₃ immediately after birth, and from birth to weaning they received the same vitamins from fresh milk, whole corn, a customized feed mix, and a milk supplement. The mean daily intake of vitamin A from birth to 6 weeks was approximately 80,000 IU and 6,300 IU of vitamin D₃, and progressively less vitamin A and D₃ was fed from 6 weeks until weaning at 3 months. The NRC recommendations for daily vitamin intake are 2100 IU of vitamin A at birth, increasing to 6360 IU at 2 months, and 330 IU of D₃, increasing to 990 IU over the same period. Experimentally, the IM injection of vitamins A and D₃ immediately after birth, and from birth to 6 months until weaning at 3 months. The NRC recommendations for daily vitamin intake are 2100 IU of vitamin A at birth, increasing to 6360 IU at 2 months, and 330 IU of D₃, increasing to 990 IU over the same period. The mean daily intake of vitamin A from birth to 6 weeks was approximately 80,000 IU and 6,300 IU of vitamin D₃, and progressively less vitamin A and D₃ was fed from 6 weeks until weaning at 3 months. The lesion is a chondrodystrophy affecting particularly the long bones and the lumbar vertebrae. Gross examination and radiography of the longitudinal slabs of the humeri, tibias, and femurs reveal focal to almost complete closure of the physs, with physs subjected to compression being more severely affected more than those subjected to tension.

**CALCINOGENIC GLYCOSIDE POISONING (ENZOOTIC CALCINOSIS)**

**SYNOPSIS**

**Etiology** Ingestion of calcinogetic glycosides in a few specific poisonous plants.

**Epidemiology** Enzootic disease in all species in regions where toxic plants occur.

**Clinical pathology** Elevated blood calcium and phosphorus concentration; tissue calcification visible on x-ray.

**Lesions** Calcification of all tissues; degenerative arthritis in all limb joints.

**Diagnostic confirmation** Identification of specific plant.

**Treatment** None.

Control Remove and keep animals away from toxic plants.

**ETOLOGY**
Calcinogetic glycosides occur in very small quantities in plant leaves. The aglycone (non-sugar) radical is a vitamin D₃ sterol, a 1,25-(OH)₂D₃-like compound. Hydrolysis of the glycoside releases the vitamin D₃ analog, causing the development of calcification of soft tissues, similar to hypervitaminosis D. The plants in which these glycosides have been identified are Solanum malacoxylon (i.e., S. glaucophyllum, S. glaucum, S. glaucescens, S. glaucumfrutescens), Nierembergia veitchii, and Cestrum diurnum (wild jessamine).

Other plants in which the presence of calcinogetic glycosides is suspected are Stenotaphrum secundatum (crab grass) in Jamaica, S. linnaeanum (= S. hermannii, S. sodomaum; apple of Sodom), S. torvum (devil's fig), and Trisetum flavescens (yellow or golden oat grass) in Europe.

The plants are weeds of pasture and are readily eaten by livestock, especially in drought years when other forage is scarce. The glycosides are very stable and resist drying and storage for periods longer than a year. Heating reduces the toxicity of Solanum malacoxylon significantly but has little effect on that of Trisetum flavescens.

**EPIDEMIOLOGY**

**Occurrence**
Enzootic calcinosis and its causative plants occur in most countries. The disease associated with Solanum spp. occurs in tropical and subtropical regions, including Africa, Argentina, Brazil, Cuba, Papua New Guinea, the West Indies, and Hawaii. Cestrum diurnum poisoning occurs in the far southern United States, especially Florida, Texas, and California. Tentative diagnoses have been made in India and Israel. In Jamaica the disease is known as “Manchester wasting disease,” in Hawaii as “naalehu,” and in South America as “espichamento” or “enteque seco.”

In Austria and Germany, T flavescens is a common component of alpine pasture and is associated with the onset of signs about 18 months after cattle are put onto the infested pasture. Resident cattle show clinical signs at about 3 years of age. The grass is most toxic when it is young, and the clinical signs are worse when the cattle are at pasture.

**Risk Factors**
Animal Risk Factors
Both sexes and all ages of all animal species are affected—ruminants most commonly, horses less so. Pigs and sucking lambs are least susceptible.

**PATHOGENESIS**
The glycoside ingested in the plant is hydrolyzed by rumen microbes, intestinal mucosal enzymes, and bone cells to form the vitamin D₃ analog. Absorption of the active substance results in a dramatic increase in the uptake of calcium from the diet. Blood levels of calcium are markedly increased, and this is followed by deposition of calcium in soft tissues. The mode of action of the glycoside is similar to that of 1,25-dihydroxycholecalciferol.

**CLINICAL FINDINGS**
The disease is chronic and may persist for several years. It is characterized by wasting, reluctance to walk, a stiff gait, constant shifting of the weight from foot to foot, and a disinclination to get up or to lie down. Forced exercise is associated with severe distress; some animals may become aggressive. Affected animals stand for long periods with the back arched and the legs stiffly extended. Calcification of blood vessels may be palpable, for example, during rectal examination. Cardiac murmurs are audible. Clinical signs subside if the animals are removed from the causative feed, but resorption of calcium

**FURTHER READING**

**REFERENCE**
deposits in tissues is minimal even years after removal from the affected pastures. Animals left on the toxic pasture eventually become recumbent and die. Fetuses may be affected.

**CLINICAL PATHOLOGY**

Serum concentrations of calcium and phosphorus increase by 20% to 25%, with increases of up to 3.4 mmol/L of calcium and 4 mmol/L of phosphorus. Tissue calcification should be detectable radiologically. Anemia is common in animals poisoned by *Solanum malacoxylon.*

**Necropsy Findings**

Non-specific emaciation, anasarca, and ascites are common. Calcification of all blood vessels, including the aorta and coronary arteries, and of the endocardium, is the most readily visible, characteristic lesion. Calcification is also present in the pleura; the lung parenchyma, which is usually emphysematous; in most other viscera; and in tendons and ligaments. Degenerative arthritis occurs in the limb joints.

**DIFFERENTIAL DIAGNOSIS**

The history, clinical findings, and discovery of specific toxic plants will provide diagnostic confirmation. Repeated overdosing with vitamin D, by injection or administration in compounded feeds, replicates the clinical and necropsy findings.

**TREATMENT AND CONTROL**

No practicable treatment is available. Careful management of affected pasture in Europe has been shown to significantly reduce the losses as a result of the disease.

**REFERENCES**

**Hypoglycin A Intoxication of Horses (Atypical Myopathy [Myoglobinuria] in Grazing Horses)**

Hypoglycin A intoxication of horses is a syndrome of acute myoglobinuria occurring in horses at pasture in Great Britain, Ireland, Europe, North America, and, possibly, Australia and New Zealand. The disease is caused by ingestion of seeds of the maple trees *Acer negundo* (box elder) in the United States and *Acer pseudoplatanus* in Europe. The toxic compound is hypoglycin A (L-α-amino-methylene cyclopropylpropionic acid), which is metabolized to methylenecyclopropylacetic acid (MCPA). MCBA can be detected in the blood of affected horses and is a potent inhibitor of multiple acyl-CoA dehydrogenases causing a specific abnormal pattern of accumulation of blood acylcarnitines and urine organic acids. This pattern was recognized in affected horses before the causative agent was identified.

The potential of other maple trees (*Acer palmapatum* [Japanese maple], *A. saccharum* [sugar maple], *A. spicatum* [mountain maple], and possibly others) to cause this disease is unknown, although these species contain, or likely contain, hypoglycin A. The disease has a strong seasonal distribution, with most, but not all, cases occurring in autumn. Occurrence of the disease is sporadic but usually affects more than one animal in a band of equids. Horses, ponies, and zebras have been affected. Localized outbreaks involving large numbers of horses are reported. Risk of the disease in Europe increases with increasing time at pasture, presence of wood or dead leaves in the pasture, lack of supplemental feeding, and presence of trees. Wind speed and speed of wind gusts is greater immediately preceding outbreaks of the disease than at other times.

There does not appear to be a breed or sex predilection to development of the disease. Younger horses might be at greater risk of the disease, but this could simply reflect the age distribution of horses at pasture in areas in which the disease occurs. Atypical myopathy occurs almost exclusively in horses at pasture and is not associated with enforced exercise.

The case-fatality rate is usually 60% to 70% but can be much higher. Prognosis is directly related to the severity of clinical signs, such as tachycardia, tachypnea, recumbency, sweating, anorexia, and dyspnea.

Clinical signs are characteristic of acute rhabdomyolysis and include an abrupt onset of stiffness and reluctance to move. Affected horses might be noticed to be depressed or have reduced activity for 1 to 2 days before onset of clinical signs. Horses can be affected up to 4 days after being removed from pasture. Progression to lateral recumbency is rapid, occurring within hours of the initial onset of signs. Recumbency is often the first indication of this disease observed in horses at pasture. Horses forced to stand have tremors and difficulty walking. Lumbar and gluteal muscles can be firm. Affected horses are tachycardic and tachypneic. Respiratory distress, presumably secondary to degeneration of intercostal muscle and the diaphragm, is common in recumbent horses in the terminal stages of the disease. There is discoloration of urine (pigmenturia). There are abnormal ventricular arrhythmias and impaired myocardial function, which can persist for at least 10 weeks in affected horses. Affected horses usually die or are euthanized within 24 to 72 hours of onset of clinical signs.

Serum biochemical abnormalities include massively increased serum activities of creatine kinase, lactate dehydrogenase, and aspartate aminotransferase. Serum concentrations of troponin T, a marker of myocardial damage, are above normal in most affected horses. Serum concentrations of vitamin E and/or selenium and red cell activity of glutathione peroxidase are not consistently abnormally low. Serum concentrations of acylcarnitines are abnormal, with elevations of concentrations of short-, medium-, and long-chain compounds. Urine concentrations of ethylmalonic acid, methylsuccinic acid, lactic acid, adipic acid, butyrylglycine, isovalerylglycine, and hexanoglycine are increased in affected horses.

The acid-base status of affected horses is a mixture of respiratory alkalosis, lactic acidosis, and strong iron difference (SIDm) alkalosis. Abnormalities in serum sodium, potassium, and chloride concentrations are usually small.

Necropsy examination does not reliably reveal gross evidence of muscle disease, although there can be swelling, edema, and localized hemorrhage into muscles. There are hemorrhagic or pale areas in the ventricular myocardium of some horses. Histologic examination reveals the presence of widespread degeneration of myocytes, without inflammation, in muscles of locomotion and respiration. Within a muscle group, some fibers are severely affected, whereas other neighboring fibers are apparently normal. The ventricular myocardium has lesions of muscle degeneration in some horses. Myoglobinuric nephrosis is a consistent finding in horses that die spontaneously or are euthanized in the terminal stages of the disease.

Definitive diagnosis is based on the presence of clinical signs of muscle disease, large elevations in serum activity of muscle-derived enzymes, and necropsy examination.

Treatment is supportive because there is no definitive antidote for hypoglycin A. Affected and at-risk horses should be removed from the pasture and prevented from eating more seeds of *A. negundo* or *A. pseudoplatanus.* Consideration should be given to administering activated charcoal to reduce absorption of further toxin from the gastrointestinal tract (500 g per 500-kg horse, orally). Some affected horses are in pain and should be administered analgesics. Hydration and electrolyte and acid-base balance should be maintained.
Administration of antioxidants and muscle relaxants is recommended but is without objective evidence of efficacy. Control centers around preventing horses and ponies from eating the seeds (samaras) of Acer negundo or A. pseudoplatanus. The seeds can be blown into pastures from trees bordering the pasture—consistent with wind speeds being higher immediately preceding outbreaks than at times when the disease did not occur.7

PLANT POISONINGS WITH KNOWN TOXINS

AMINOPROPIONITRILE
3-Aminopropionitrile is a poisonous substance found in Lathyrus spp. (wild peas), for example, Lathyrus hirsutus (wild winter pea), sometimes sown with grasses to provide early spring grazing. Signs of toxicity in cattle grazing mature plants bearing seed pods consist of salivation, sawhorse stance, head held low, continuous head and ear movements, trance-like gaze, diminished responsiveness, reluctance to move, pain in the feet causing lameness, sitting with the feet under the body, and a marked disinclination to rise. Other signs include lameness, stumbling gait, recumbency, and paddling convulsions. The signs are exacerbated by driving or other stimulation. Necropsy findings are limited to nonspecific lesions such as pulmonary congestion.

PLANT POISONINGS WITH SUSPECTED OR UNIDENTIFIED TOXINS

JUGLONE
Juglone, a poisonous resinoid found in the shavings of Juglans nigra (black walnut tree), has been suspected as being associated with lameness and edema of the lower limbs in horses bedded on the shavings, but juglone is present in the bark and leaves, not the heartwood from which the shavings are made. The lesions are produced by an increase in local capillary blood pressure. A similar syndrome is associated with Berteroa incana (hoary alyssum). Swelling of the distal limbs and fever are consistent signs associated with ingestion of this plant. Signs appear 18 to 36 hours after ingestion of the plant and disappear 2 to 4 days after the plant is removed. Abortions have been reported but may be secondary to the high fever. An alternative syndrome of severe gastroenteritis plus intravascular hemolysis is also recorded in horses fed hay contaminated by Berteroa incana.

MYOPATHY—WITH GAIT INCOORDINATION, RECUMBENCY, ELEVATED CPK
• Karwinskia humboldtiana—coyotillo
• Small amounts of Senna (= Cassia) spp. ingested over a long period are associated with skeletal muscle myopathy and/or paralysis. In Senna occidentalis poisoning in horses and goats, the early signs are anorexia and diarrhea followed by hyperpnea, tachycardia, ataxia, staggering, and recumbency. At autopsy there is a fatal cardiomyopathy. The muscle lesion is accompanied by marked elevations of SGOT and CPK levels. Similarly, in pigs, early diarrhea may be followed by lateral recumbency and skeletal muscle myopathy.

ALUMINUM TOXICOSIS
Aluminum is one of the potentially toxic elements introduced into the diets of animals by the deposition of soluble salts in acid rain, powder particles in factory effluent, accidental dosing, or absorption by plants.

Case reports in large animals are rare, and most of the toxicologic information comes from human data or investigational studies using rats, mice, and rabbits. Frank et al. reported polioencephalomalacia associated with elevated aluminum levels in Simmental calves,3 and Easterwood et al. reported phosphine gas generation in horses accidentally receiving aluminum phosphate in their feed.5 It should be pointed out that the toxin associated with aluminum phosphate intoxication is the toxic gas phosphine and not aluminum.

Absorption of aluminum is poor following oral, dermal, and inhalation exposure. Following absorption, it is distributed to other tissues, with the highest concentration in the bone.7 Chronic exposure to aluminum results in sequestration in the bone, from which it is slowly released. Aluminum readily crosses the blood–brain barrier and placentary barrier, resulting in neurotoxicity and developmental toxicity.10 Excretion is through the urine, with very little bile and fecal excretion.

Clinical signs depend on specific organs, but deposition in the bone is associated with osteoarthritis and anemia. Other organs affected include the heart (myocardial infarction), brain (cognitive dysfunction and other neurotoxic effects), liver, and kidney.

There is no treatment, and diagnosis depends on finding aluminum in the liver and kidney. Aluminum levels of 6 to 11 ppm in the liver and 4 to 5 ppm in the kidney of sheep and cattle are considered toxic amounts.

FLUORIDE TOXICOSIS

SYNOPSIS
Etiology Toxic amounts of fluoride are found in water (naturally or contaminated), soil, and plants contaminated by industry pollution, mineral mixes with excessive fluoride, and older insecticides, anthelmintics, and rodenticides containing sodium fluoride, sodium fluorosilicate, and sodium fluoracetate. Fluoroacetate may also be found in several plant species, such as Dichapetalum spp., Gastrolabium spp. Oxylobium spp., and others.

Epidemiology Most often associated with continuous ingestion of small but toxic amounts of fluoride in the diet or drinking water.

Clinical pathology Elevated serum and urine levels of fluoride; elevated serum levels of Ca, BUN, and ALP in some cases.

Lesions Live animals: Dental fluorosis—mottling and erosion of permanent teeth. Osteofluorosis with lameness and unthriftiness.
ETIOLOGY
Fluoride is present in some concentration in almost all animal feed and water sources, so exposure not only occurs but continues throughout the lifetime. Both acute and chronic poisoning occur. Acute toxicity in large animals is very rare and generally occurs after exposure to an older commercial product, such as sodium fluoride, sodium fluorosilicate, or sodium fluoroacetate, or to volcanic ash. Chronic toxicosis is associated with the ingestion of high-fluoride-containing rock salt phosphate supplements, fluoride-contaminated forage or soil, and water either naturally containing excess fluoride or that has been contaminated with fluoride. The severity of the poisoning depends on the amount ingested, the solubility of the fluoride compound, the species, diet, and the animal’s age. Death losses are rare and restricted largely to acute poisoning, with the major losses taking the form of unthriftiness associated with chronic fluorosis.

EPIDEMIOLOGY
Occurrence
Fluoride intoxication has been observed in most countries, usually in association with specific natural or industrial hazards. In Europe and Great Britain, losses are greatest on summer grazing of pastures contaminated by industrial fumes, including dust from factories converting rock phosphate to superphosphate and effluent from aluminum smelters. Iceland and parts of the southern Andes Mountains are extensively affected by contamination from volcanic ash. Drinking water from deep wells, industrial contamination of pasture, and the feeding of fluoride-bearing phosphatic supplements are the common associations in North America. Deep wells also are an important source in Australia and South America. In Africa the important association is the feeding of phosphatic rock supplements.

In experimentally induced fluorosis in cattle, mottling of the tooth enamel occurs at intakes of 27 mg/kg in the diet, but there is no pitting until levels of 49 mg/kg are fed. Bony lesions are slight at intakes of 27 mg/kg, moderate at 49 mg/kg, and marked at 93 mg/kg, and milk production in dairy cows is thought not to be affected by intakes of 50 mg/kg of fluoride in the diet until about the fourth lactation. A more recent view is that the existing tolerance level for dairy cows of 40 mg/kg is too high and will lead to serious loss of production and some dental fluorosis in high-producing cows. Risk Factors

Animal Risk Factors
Host factors are age and species. Daily intakes of 0.5 to 1.7 mg/kg BW of fluoride as sodium fluoride produce dental lesions in growing animals without affecting general well-being. Intakes equal to twice these amounts are consumed by adult animals without ill effect. In heifers a continuous intake of 1.5 mg/kg BW per day is sufficient to be associated with severe dental fluorosis without affecting growth rate or reproductive function. However, extensive osteofluorosis and periods of severe lameness will occur. The fluoride content of the bones of newborn calves depends on the dam's intake of fluoride in the last 3 to 4 months of pregnancy and not on her own bone composition.

Most recorded occurrences of fluorosis are in cattle. Sheep are less susceptible than cattle, and it is rarely reported in horses. A continuous intake of 1 mg/kg BW is the maximum safe limit for ruminants; an intake of 2 mg/kg BW produces clinical signs. In pigs an intake of 1 mg/kg BW added fluoride for long periods has no deleterious effect. Fetal effects are small. The current view is that placental passage is infinitesimal in amount, but historically, cases of neonatal dental fluorosis have been identified in cattle. Fluoride does not occur in significant quantities in the milk or colostrum of poisoned cows. Environmental Risk Factors

Fluoride occurs naturally in rocks, particularly those from North Africa, are rich in fluoride (0.9% to 1.4%). Nonphosphatic limestones contain insignificant amounts.

Supplementary Feeding of Phosphates
The common occurrence of phosphorus deficiency in animals has led to the search for cheap phosphatic materials suitable for animal feeding. Rock phosphates are commonly used, and many deposits contain dangerous amounts of fluoride (3% to 4%). The fluoride content of the mineral can be reduced, but the cost encourages the use of marginally safe material. The major occurrence of water-borne fluoride intoxication is from water obtained from deep wells or artesian bores. The available data suggest that although minor tooth lesions occur at 5 mg/kg of fluoride, it is not until levels of 10 mg/kg are exceeded that excessive tooth wear occurs and the nutrition of the animal is impaired. More serious systemic effects do not occur until the water contains 30 mg/kg.

Miscellaneous sources of fluoride include the ingestion of superphosphate itself, but a
supernatant liquid of a suspension of the fertili-zer will contain no fluoride. Some wood preservatives may contain large quantities of fluoride, which may be associated with acute poisoning in some circumstances.

Farm Risk Factors
Animals that are housed in the winter and grazed only during the summer and fall on pasture contaminated by factory effluent may show considerable clinical improvement in clinical signs during the winter and an annual recurrence of signs when the animals are outside. 1

Human Risk Factors
Although it is possible for animal tissues to contain amounts of fluoride in excess of permissible amounts, this is not usually so in chronic fluorosis. The fluoride content of milk in these circumstances is below that permitted in fluoridated drinking water (1 mg/L).

PATHOGENESIS
Absorption from the gastrointestinal (GI) tract depends on the form ingested, with soluble forms such as sodium fluoride being more bioavailable than fluoride found in contaminated feed, soil, or water. Once absorbed, fluoride is distributed throughout the body, primarily to bone and teeth. Excretion is renal. 10

Acute intoxication, as a result of the ingestion of large amounts of soluble fluorides (e.g., sodium fluoride), occurs rapidly, with signs appearing 30 to 60 minutes after ingestion. The mechanism of action is unknown but may be attributable to the development of hydrofluoric acid in the GI tract, onset of systemic hypocalcemia, decreased Na/K ATPase activity, or the inhibition of glycolysis. 19

Chronic ingestion results in the deposition of fluoride in the bones and/or teeth of affected animals. 1 Deposition in bone occurs throughout life but in teeth only in the formative stages. 1,7 In bones, fluorides alter throughout life but in teeth only in the formative stages. 1,7 In bones, fluorides alter through mineralization, crystal structure, and remodeling of bone by replacing hydroxyl groups in the hydroxyapatite of the bone crystalline structure. The degree of deposition varies, being greatest on the periosteal surface of the long bones where exostoses commonly develop. These bony changes are often referred to as skeletal fluorosis or osteofluorosis.

During tooth formation, fluorides inhibit the action of ameloblasts and odontoblasts, resulting in failure of the developing tooth to accept minerals. Thus tooth lesions occur only if the intake is high before the teeth have erupted, but bone lesions occur at any stage. When the tissue levels of fluoride are moderate, characteristic lesions as a result of hypoplasia of enamel appear in the teeth. During this time the fluoride levels in bone can increase slowly without appreciable bone changes. The facility of storage in bone explains the long latent period that occurs in animals subjected to chronic intoxication. Lesions generally begin on the medial side of the proximal metatarsal bones and expand to include the mandibles, metacarpal bones, and ribs. Abnormalities, once they occur, result in lameness and are generally symmetric and bilateral. 1 At very high levels the storage capacity of bone and teeth is exceeded, and blood and urine levels rise. The bone lesions of osteomalacia and osteoporosis, with accompanying pathologic fractures, are associated with excessive mobilization of calcium and phosphorus to compensate for their increased urinary excretion in conjunction with fluoride.

The kidney is the primary tissue affected, but other tissues in which degenerative changes may occur are the bone marrow, adrenal glands, heart muscle, and central nervous system. 2,10,11 A severe anemia may rarely occur as a result of toxic depression of bone-marrow activity, although this is not a constant or expected sign.

CLINICAL FINDINGS
Acute Intoxication
The syndrome includes dyspnea, complete anorexia, vomiting, and diarrhea in pigs and ruminal stasis with constipation or diarrhea in ruminants. 1,4 Vomiting acts as a protective mechanism, and toxic doses in pigs may be eliminated in this way without the development of other signs. Nervous signs are characteristic and include ataxia, muscle tremors and weakness, a startled expression, pupillary dilation, hyperesthesia, and constant chewing. Tetany, convulsions, and collapse and death follow within a few hours.

Chronic Intoxication
Because of the distinct clinical separation between animals with dental lesions and those that have, in addition, signs of lameness and general ill-health, it is customary to refer to two forms of the disease: dental fluorosis and osteofluorosis. Lesions of the teeth and bones are characteristic, and the signs are largely referable to these lesions. Tooth changes are the earliest and most diagnostic sign but may not produce clinical effects until other signs have developed. 1 Thus tooth changes are the earliest and most diagnostic sign but may not produce clinical effects until other signs have developed. Consequently, they are often missed until other clinical findings suggest that the teeth be examined.

Dental Fluorosis
The permanent teeth exposed to intoxication before eruption will be affected and perhaps those of animals exposed in utero. The earliest and mildest sign is mottling with the appearance of pigmented (very light yellow, green, brown, or black) spots or bands arranged horizontally across the teeth. Occasional vertical bands may be seen where pigment is deposited along enamel fissures. Mottling and staining occur on incisors and cheek teeth and are not evident when the affected tooth erupts, and in fact they may not appear until some months later. The cheek teeth are usually more dramatically affected than the incisors but are very difficult to examine clinically. If the period of exposure to intoxication has been limited only some of the teeth may be affected, but the defects will always be bilateral.

Mottling may not progress any further, but if the intoxication has been sufficiently severe, defective calcification of the enamel leads to accelerated attrition or erosion of the teeth, usually in the same teeth as the mottling. The mottled areas become pits, and the teeth are brittle and break and wear easily and unevenly. Patterns of accelerated attrition are dependent on the chronicologic occurrence of the intoxication and the eruption time of the teeth. Uneven and rapid wear of the cheek teeth makes proper mastication impossible. Infection of the dental alveoli and shedding of teeth commonly follow. The painful condition of the teeth and inability to pretend and masticate seriously reduce the food intake and are associated with poor growth in the young and unthriftness and acetonemia in adults. Affected cattle may lap cold drinking water to avoid the discomfort occasioned by normal drinking. Eruption of the teeth may be abnormal, resulting in irregular alignment.

A standard for the classification of fluoro-sis has been proposed based on the degree of mottling, pitting, and rate of wear of the teeth. The effects of dental mottling, pitting, and excessive wear of incisors can be used to estimate the exposure periods of cattle during ontogenesis. The additional c finally apparent abnormalities include delayed eruption of permanent incisor teeth, necrosis of alveolar bone resulting in recession of bone and gingiva, oblique eruption of permanent teeth, hypoplasia of teeth, wide spaces between teeth, and rapid development of any dental lesions.

Osteofluorosis
Lameness most marked in the loins, hip joints, and hindlimbs and unthriftness in animals of any age are the signs usually observed first. 1,12 The occurrence of hip lameness or fractures of the third phalanx on a herd scale in cattle is thought to be diagnostic of fluorosis. Pain is evinced on pressure over limb bones and particularly over the bulbs of the heels. The bones may be palpably and visibly enlarged. This is most readily observed in the mandible, sternum, metacarpal, and metatarsal bones and the phalanges. This overall thickness may be subsequently replaced by well-defined exostoses. The bones are subject to easy fracture. These well-defined lesions occur only in advanced cases and are often accompanied by extensive tooth lesions in young animals. In addition to the cases affected by
generalized lameness, there are cases that show a sudden onset of very severe lameness, usually in a forelimb, associated with transverse fracture of the third phalanx.

**Other Effects**

Reproduction, milk yield, and wool growth are not usually considered to be adversely affected except indirectly by the reduced food intake. Severely lame animals may have lowered reproductive performance indirectly as a result of physical dysfunction that interferes with mating.

Additional signs, including diarrhea and anestrus and other forms of infertility in cattle, diarrhea in sheep, and polydipsia in pigs, are recorded in the naturally occurring disease but cannot be considered as constant or pathognomonic. Horses with chronic fluorosis have lameness; dental lesions, including excessive molar abrasion; and hyperostotic lesions of the metatarsus, metacarpus, mandible, and ribs.

**CLINICAL PATHOLOGY**

Normal cattle have blood levels of up to 0.2 mg fluoride per mg/dL of blood and 2 to 6 mg/kg in urine. Cattle on fluoride intakes sufficient to cause intoxication may have blood levels of 0.6 mg/dL and urine levels of 16 to 68 mg/kg, although blood levels are often normal. Such high levels may not be an indication of high intakes immediately preceding the examination because heavy deposits in bones may be associated with abnormally high blood and urine fluoride levels for some months after the intake has been reduced to normal. Urine levels should be corrected to a specific gravity of 1.040.

Serum calcium may be low or normal; phosphorus levels are usually normal, and there is a significant correlation between the amount of fluoride fed and the concentration of alkaline phosphatase in the serum. The increase in phosphatase activity is probably related to the abnormal formation of bone and may be 3 to 7 times the normal level.

Radiographic changes of bones containing more than 4000 mg/kg of fluoride include increased density or abnormal porosity, periosteal feathering and thickening, increased trabeculation, thickening of the compact bone, and narrowing of the marrow cavity. Spontaneous rib fractures show incomplete union. Good data are available for fluoride concentrations in rib bones, and estimations of fluoride content in biopsy samples of ribs have been used in the clinicopathologic study of the disease. Samples of tail bone and the spongiosa of the tuber coxae have also been used for these purposes.

**Necropsy Findings**

Severe gastroenteritis is present in acute poisoning, and there may be degenerative changes in the renal tubular epithelium. In chronic fluorosis the bones have a chalky, white appearance; are brittle; and have either local or disseminated exostoses, particularly along the diaphyses. Intraarticular structures are not primarily affected, although there may be some spurring and bridging of the joints. Histologically, there is defective and irregular calcification of newly formed trabecular bone and active periosteal bone formation. Hypoplasia of the enamel and dentin are consistent physical and histologic defects in the teeth of affected young animals. Young animals may also develop thickened growth plates and widened metaphyses that are grossly similar to rachitic changes. Degenerative changes in kidney, liver, heart muscle, adrenal glands, and central nervous system have been reported in severe cases. Degeneration of the bone marrow and consequent aplastic anemia also occur.

Chemical examination of necropsy specimens is valuable in the diagnosis because the fluoride content of bones from poisoned animals is greatly increased. Levels of up to 1200 mg/kg of bone on a dry, fat-free basis are observed in normal animals but may be increased up to 3000 mg/kg in animals exposed to fluoride and showing only motting of the teeth. Animals showing severe clinical signs have levels greater than 4000 mg/kg of bone on a dry, fat-free basis; after prolonged heavy feeding, levels may be as high as 1.040.

Care must be taken in selecting the bone samples because of the great variation in the concentration of fluoride that occurs between different bones. Good data are available for comparison between metacarpal, metatarsal, rib, pelvic, and mandibular bones and antlers of deer. Mandibles usually show the greatest concentrations; in the long bones, the distal and proximal quarters are more sensitive indicators than the center half.

Diagnostic confirmation depends on fluoride assay of forage, soil, or water; blood and urine of affected animals; and bones and teeth at necropsy.

**Samples for Confirmation of Diagnosis**

- **Toxicology**—mandible/metacarpal/metatarsal, rib, vertebrae for evidence of osteofluorosis; urine from affected animals for evidence of recent exposure (ASSAY [F])
- **Histology**—formalin-fixed metacarpal/metatarsal/mandible (LM)

**DIFFERENTIAL DIAGNOSIS**

**ACUTE:**

- Heavy metal toxicity
- Nephrotoxic mycotoxicosis
- Oak (Quercus spp.) toxicity
- Plant toxins (Amaranthus spp., Isotropis spp., Lantana spp.)

**CHRONIC:**

- Chronic selenium toxicity
- Degenerative joint disease/osteoarthritis

**TREATMENT**

Treatment, apart from removing the animals from the source of fluoride, is largely impractical and supportive in nature. In acute ingestions, most animals die before there is time for treatment. With chronic ingestions, no improvement in dental or osseous lesions can be anticipated, but there may be amelioration of the other clinical signs. Activated charcoal is not recommended because fluoride does not bind well to it. Calcium, magnesium, or aluminum may be used to bind hydrofluoric acid produced in the stomach, and because of their insolubility they are safe even in large quantities. Intravenous calcium should be used if hypocalcemia or tetany are present.

**CONTROL**

- Where fluoride levels are marginal, careful husbandry, including the watering of young growing stock on fluoride-free supplies, permitting only adults to be watered on the dangerous supplies, and rotating the animals between safe and dangerous waters at 3-month intervals, may make it possible to utilize land areas otherwise unsuitable for stock raising. In some areas, dairy herds may have to be maintained by the purchase of replacements rather than by the rearing of young stock. In areas where long-term ingestion of fluoride is likely to occur, the aim should be to provide a diet of less than 50 mg/kg of the total diet of dairy cows. Adequate calcium and defluorinated phosphorus intakes should be ensured because these reduce bone storage of fluoride.

- Phosphate feed supplements should contain no more than 0.2% fluoride for milking or breeding cattle or 0.3% for slaughter cattle, and they should not comprise more than 2% of the ration if the fluoride content is of this order. Some deposits of rock phosphate have much higher contents of fluoride than others, and commercial defluorination makes these toxic deposits safe for animal feeding.

- Bone meal in some areas may contain excessive quantities of fluoride and should be checked for its fluoride content.

- Water from deep wells and artesian bores should be assayed for fluoride content before use. The fluoride content of drinking water can be reduced (from 10 to 0.95 mg/kg) by adding freshly
slaked lime to the water; 500 to 1000 mg/kg should be added, and the water must be allowed to settle for 6 days. The method requires the use of large storage tanks.

- Aluminum salts are the principal substances used to detoxicate food and water. They are unpalatable and relatively ineffective, reducing the accumulation of fluoride in bone by only 20% to 30%, and are thus referred to as “alleviators.” Extensive field trials of aluminum as an alleviator have not justified its use as a practicable control measure in average circumstances.

Congenital Defects of Muscles, Bones, and Joints

Defects of the musculoskeletal system are among the most common congenital abnormalities in farm animals. In cattle, 476 such defects are listed. Many of them are lethal, and most of the remainder are life-threatening because of interference with grazing or the prehension of food. Many of them occur in combinations, and thus single defects are uncommon. For example, most axial skeletal defects and cleft palates occur in calves that already have arthrogryposis.

Because of the very large volume of literature involved it is not possible to deal with all the recorded defects here, and the text is limited to those defects that are thought to be of general importance. Whether or not they are inherited or have an environmental cause is often not known, and thus an etiologic classification is not very effective—nor is an anatomic or pathologic classification, so we are reduced to a classification based on abnormal function.

WEAKNESS OF SKELETAL MUSCLES

A number of sporadic myopathies are recorded in cattle and sheep. Causes have not been determined in most of them. Splayleg in pigs has been well described and occurs in most countries.

CONGENITAL HYPERPLASIA OF MYOFIBER

There is only one identified state of congenital hyperplasia; it is the inherited form of doppelender, double muscling, or culard of cattle, described under “Myofiber hyperplasia.” The principal cause of the bulging muscles is an increase in the number of myofibers in the muscle.

OBVIOUS ABSENCE OR DEFORMITY OF SPECIFIC PARTS OF THE MUSCULOSKELETAL SYSTEM

Some of these defects are inherited and include the following:
- Achondroplastic dwarfism, inherited miniature calves, bulldog calves
- Umbilical or scrotal hernia, cryptorchidism
- Tail deformity (kinking), taillessness
- Reduced phalanges, including hemimelia (individual bones missing), amputates (entire limbs missing), vestigial limbs (all parts present but limbs miniaturized)—amputates in outbreak form are recorded in cattle and produced experimentally by irradiation injury of sows, cows, and ewes during early pregnancy
- Inherited arachnomyelia (spiderly limbs) of calves
- Congenital thickleg of pigs, osteoporosis of calves, muscular hypertrophy of calves
- Cyclopaean deformity—the inherited form is associated with prolonged gestation. The toxic form associated with ingestion of Veratrurn californicum.
- Displaced molar teeth, mandibular prognathism—agnathia in lambs takes a variety of forms, including complete absence of the lower jaw and tongue.

FIXATION OF JOINTS

Because arthrogryposis, which has been used to convey the description of joint fixation, strictly means fixation in flexion, the term congenital articular rigidity has been introduced. The immobilization of the joint may be attributable to lack of extensibility of muscles, tendons, ligaments, or other tissues around the joint; to deformity of articular surfaces; or, theoretically, to fusion between the bones at the articular surface. Muscle contracture, which is the principal cause of joint fixation, has been produced experimentally and occurs naturally as a result of primary muscle atrophy or of atrophy resulting from denervation. Articular surface deformity is usually associated with gross deformity of the limb bones and is usually identifiable, but the principal problem in the diagnosis of congenital articular rigidity is to determine what the pathogenesis might have been and, beyond that, what was the specific cause.

Congenital fixation of joints can be caused by some well-known entities, as follows.

Cattle
- Hereditary congenital articular rigidity (HCAR) with cleft palate in Charolais
- HCAR with normal palates in Friesians, Danish Reds, Swedish, Shorthorns
- Inherited arthrogryposis
- Inherited multiple-tendon contracture
- Sporadic cases of congenital joint deformity as described for foals
- Inherited multiple ankylosis of Holstein–Friesian cattle
- Environmentally induced congenital articular rigidity caused by the following:
  - Intrauterine infection with Akabane virus
  - Ingestion of lupins
  - Ingestion of Astragalus and Oxytropis spp. (locoweed)
  - Sorghum, Johnson grass, Sudann grass
  - Dietary deficiency of manganese

Sheep and Goats
- Inherited congenital articular rigidity in Merino sheep
- Infection with Akabane virus
- Infection with Schmallenberg virus
- Poisonous plants as for cattle
- Poisoning with parbendazole and cambendazole.

Foals
- “Contracted” foals having congenital axial and appendicular contractures of joints have been reported in the United States; the cause unknown, but it is not thought to be inherited. Deformities include torticollis, scoliosis, and thinning of ventral abdominal wall, sometimes accompanied by evagination, asymmetry of the skull, and flexion contracture in distal limb joints.
- Congenital articular rigidity also occurs in foals from mares fed on hybrid Sudan grass pastures.
• Sporadic cases of congenital joint deformity occur in foals and calves. They are manifested usually by excessive flexion of the metacarpophalangeal joints, causing affected animals to “knuckle” at the fetlocks and sometimes walk on the anterior aspect of the pastern. A similar defect occurs in the hindlegs. Many mild cases recover spontaneously, but surgical treatment may be required in badly affected animals. The cause in these sporadic cases is unknown, and necropsy examination fails to reveal lesions other than excessive flexion of the joints caused by shortening of the flexor tendons. Rarely such fixations are associated with spina bifida or absence of ventral horn cells of the spinal cord.

Piglets
• Inherited congenital articular rigidity
• Nutritional deficiency of vitamin A
• Poisonous plants, hemlock (Conium maculatum), Prunus serotina, limon weed (Datura stramonium), tobacco wastes

CONGENITAL ARTHROGROPYOSIS AND HYDRANENCEPHALY, AKABANE DISEASE, CACHE VALLEY VIRUS DISEASE, SCHMALLENBERG VIRUS

SYNOPSIS

Epidemiology Transmission by hematophagous insects. Outbreaks occur when cattle or sheep are infected in early pregnancy.

Clinical findings Teratogenic pathogen that results in abortions, stillbirths, and birth of calves (Akabane virus, Schmallenberg virus) and lambs or kids (Cache Valley virus, Schmallenberg virus) with skeletal deformities and neurologic disorders (arthrogrospy-hydranencephaly syndrome).

Necropsy findings Necrotizing nonsuppurative encephalomyelitis and polymyositis. Arthrogrospy and hydranencephaly.

Control Vaccination or exposure of breeding females to natural infection before pregnancy.

ETIOLOGY

Akabane virus and Cache Valley viruses are both members of the genus Orthobunyavirus in the family Bunyaviridae, with Akabane virus and Schmallenberg virus being members of the Simbu serogroup of the genus Orthobunyavirus and Cache Valley virus being a member of the Bunyamwera serogroup of the genus Orthobunyavirus. There are a large number of members of the Orthobunyavirus genus, and several can produce clinically inapparent infections in ruminants, but Akabane virus and Cache Valley virus produce fetal disease when they infect the dam in early pregnancy. There are subtypes of these viruses.

Other Bunyaviruses that have been associated with natural or experimentally produced fetal disease in ruminants include the following:
• Simbu serogroup—Aino and Peaton viruses
• Bunyamwera serogroup—Main Drain viruses
• California serogroup—LaCrosse and San Angelo viruses

Antibodies to the related, but as far as is known nonpathogenic, Australian Douglas virus and Tinaroo virus have been detected in cattle, sheep, goat, buffalo and deer.

EPIDEMIOLOGY

Occurrence Akabane
Serologic studies suggest that infection occurs in cattle, sheep, goats, horses, donkeys, camels, pigs, and bufaloes, but disease occurs only in calves, lambs, and goat kids.

The disease is most common in calves and has been recorded as the cause of epizootics of abortion, stillbirths, and congenital malformation in calves, with high attack rates in affected herds in two north-south geographic bands. The first band extends from Japan/Korea through Taiwan to Australia.1,2 The second band extends from the Middle East to South Africa. Congenital disease in lambs is less common but is recorded in Israel and Australia. The virus has also been isolated from insect vectors in Africa and is the probable cause of the “rigid lamb syndrome” in Zimbabwe.

Serologic surveys suggest widespread distribution of the virus in the Middle East, Asia and South East Asia, and in parts of Africa. Whereas infection in adult cattle is common in endemic areas, reports of clinical disease are rare, but neurologic disease associated with infection in cattle 2 to 7 years of age has been observed. Akabane viruses have been divided genetically into four groups (I to IV), with group I being further divided into two subgroups (Ia, Ib).3,4 Genogroup Ia strains are found primarily in Japan and Taiwan and appear to have a stronger neurovirulence than genogroup II strains that have been isolated from Japan and Korea. Genogroup Iib strains have been isolated in Japan and Israel. Genogroup III strains have been isolated from Queensland in Australia, whereas a strain isolated in Kenya represents genogroup IV.3,4

Cache Valley
There is serologic evidence that infection occurs in sheep, goats, horses, cattle, pigs, and several wildlife species but clinical disease is recorded only in sheep. The disease in sheep is recorded as an occasional epizootic in flocks in North America. Cache Valley virus is one of the more common Orthobunyaviruses in North America and has been isolated from mosquito pools collected in 22 states and several provinces in Canada and Mexico and also in Central and South America. Cache Valley is an agricultural valley in northern Utah and southeast Idaho in the United States.

Schmallenberg
A new disease in dairy cattle was identified in autumn 2011 in northwest Germany and the Netherlands. Viral genome sequences were identified in pooled blood from three affected sick dairy cows from a farm near Schmallenberg in northwest Germany, hence the name Schmallenberg virus (SBV). Serologic studies indicate that SBV was not present in domestic ruminants in northern Europe before 2011, and that the epizootics constituted introduction of the new virus into a susceptible population. Genomic studies indicate that SBV belongs to the species Sathuperi and may represent the ancestor of the reassortant Shamaunda virus.

Antibodies against SBV have been identified in roe deer, red deer, European fallow deer, mouflons, bison, New World camelds, and wild boar in northern and west-central Europe.1

Aino and Shamaunda
Aino virus is present and thought to be a cause of disease in Australia, Japan, and Israel. Serologic studies in Australia show a similar distribution in cattle to Akabane but at a lower prevalence, and clinical disease is much less common than with Akabane virus. Aino virus and Shamaunda virus can induce congenital malformations in sheep and goats.

Source of Infection
The viruses are maintained through a cycle involving vectors, in which there is probably transovarial transmission, and a susceptible vertebrate population. Replication occurs in both vertebrate and insect populations.

Akabane
Viremia in cattle is short-lived, lasting 1 to 9 days, and long-term carriers are not thought to occur. Herbivores appear essential to the vector–virus–host cycle, and there is serologic evidence of infection in cattle, sheep, goats, camels, horses, and bufaloes. In endemic areas, breeding females are infected before their first pregnancy, and therefore clinical signs are not observed in their offspring. Clinical signs occur at the north and south end of the two bands, where weather...
effects determine expansion of vectors out of the endemic region. This accounts for intermittent "outbreaks" of congenitally affected calves in southern Australia, Japan, and Korea.

In Australia, transmission is by the bites of midges Culicoides brevitarsis and C. neculosus. The virus has been isolated from C. brevitarsis, and this is probably the major vector; serologic data in Australia show that most identified infections are within the known habitat of C. brevitarsis. Vertical infection occurs, but introduction of the virus into the bovine uterus in semen causes no developmental defects. Ruminants do not become persistently infected.

The vectors for Akabane disease in Japan and Korea are C. brevitarsis, Culicoides oxystoma, Aedes vexans, and Culex tritaeniorynchus.

**Cache Valley**
The Cache Valley virus has been isolated predominantly from mosquitoes. The primary amplifying vertebrate hosts are unknown, but white-tailed deer are suspected to play a role as a disease reservoir.6

Schmallenberg
Biting midges, including C. dewulfi, C. chiopterus, and C. obsoletus complex are thought to be important vectors for SBV transmission in Belgium and Denmark and presumably contiguous countries.

Aino
Aino virus has been isolated from mosquitoes and midges, including C. brevitarsis. Serologic studies show antibody in cattle, sheep, goats, and buffalo but not camels, dogs, or horses.

**Host and Environmental Risk Factors**
The seasonal and geographic pattern of epizootics of abortions and premature births are determined by the distribution of vectors and the availability of susceptible ruminant populations in early pregnancy. Global warming is thought to be contributing to extension of vectors into geographic regions north and south of the typical infection belts and therefore disease epidemics.1,3,7

**Zoonotic Implications**
*Buynavirus* infections occur in humans from bites from infected insect vectors.

**Experimental Reproduction**
Disease has been reproduced by inoculation into early-pregnant cattle, sheep, and goats.

** PATHOGENESIS**

**Akabane**

Viremia occurs in the dam for 2 to 4 days, with an antibody peak 4 to 5 days after the viremia and a subsequent secondary rise. The dam is unaffected, but there is a focal viral persistence in cotyledons and subsequent viremia in the fetus.

Inflammatory and degenerative lesions occur in the central nervous system, but tissue tropism and damage are determined by the age of the fetus and its ability to mount an immune response. Three forms, or principal manifestations, of the disease in an affected herd are described. The first is arthrogryposis occurring in calves infected at an older age than others (fetus infected at 105 to 174 days of pregnancy). The second is arthrogryposis accompanied by hydranencephaly. The third is hydranencephaly only (infected between days 76 and 104 of pregnancy).

With arthrogryposis, there is almost complete absence of ventral horn cells in the spinal cord and an accompanying neurotropic failure of muscle development. Contracture of the joints results. The hydranencephaly is manifested by a partial or complete failure of development of the cerebral cortex. The brainstem and cerebellum are usually normal.

Several other manifestations have been described. They include prearthrogryposis groups of calves with incoordination and a mild to moderate nonsuppurative encephalitis, along with other calves with flaccid paralysis and active secondary demyelination in motor areas of the spinal cord. Some calves are unable to stand and have thickened dorsal cranial bones, hydranencephaly involving anterior and midbrainstem, and a diminutive cerebellum. The infection with Akabane virus is also credited with causing abortion, stillbirth, and premature birth. There are reports from Japan and South Korea where encephalomyelitis as a result of Akabane virus is thought to have been acquired after birth,2,4 and experimental inoculation of young calves with the Iriki variant of Akabane virus has induced encephalitis.

Lesions in the ewes during early pregnancy (days 32 to 36) include skeletal muscle atrophy and degeneration, and inflammatory and degenerative lesions in the cerebrum; the lesions in the central nervous system vary from porencephaly to hydranencephaly. There are also brachygnathism, scoliosis, hypoplasia of the lungs, agenesis or hypoplasia of the spinal cord, and arthrogryposis. Lesions are also present in fetuses of ewes inoculated between 29 and 45 days of gestation.

**Cache Valley**

Ovine fetuses are susceptible to the teratogenic effects between 28 and 48 days of gestation.7 Destructive lesions occur in the central nervous system, but infection of fetal membranes with a reduction in the volume of amniotic fluid and constriction by membranes around the fetus are thought to contribute to the occurrence of arthrogryposis.

**Schmallenberg**

The acute phase of infection in adult ruminants produces a viremia of 5 to 6 days in duration.10 In utero infection of the lamb appears to be determined by the absence or presence of a functional blood–brain barrier, explaining the window for experiment infection of 28 to 50 days (placentomes are initially present on day 28; the blood–brain barrier becomes functional on day 50 of gestation).

Arthrogryposis is secondary to transplacental infection resulting in abnormal development of motor neurons of the ventral horn.
Embryonic deaths, abortions, stillbirths, and arthrogryposis–hydranencephalopathy syndrome in newborn lambs and kids are the most common clinical abnormalities observed following infection of pregnant ewes and does. These abnormalities in lambs and kids are almost identical to those produced by Akabane virus in calves. Teratogenic effects were also observed in cattle, but at a much lower rate than in sheep and goats. A presumptive diagnosis of SBV teratogenicity is made in lambs, kids, and calves in Europe if stillbirth, premature or mummified fetuses, or abnormal neonates present with two or more of the following abnormalities: arthrogryposis, hydranencephaly, torticollis, scoliosis, kyphosis, brachygnathia inferior, muscle atrophy, joint malformations, ataxia, paresis, behavioral abnormalities, or blindness.

**CLINICAL PATHOLOGY**

The presence of specific antibody in fetal sera or the precolostral sera of neonates is diagnostic, but its absence does not exclude the diagnosis if infection precedes the development of immunologic competence. Precolostral sera from several animals should be tested, and most cases are positive at high titer. A rising titer with paired samples from the dam, or a high titer in the serum of surviving neonates, is suggestive of recent infection but not confirmatory for disease. Serologic tests include microneutralization, hemagglutination inhibition, agar gel immunodiffusion (AGID), and an ELISA test.

Virus can be detected using real-time RT-PCR and culture in specific cell lines. RT-qPCR testing of blood is of reduced value because the period of viremia is short, but brainsample material provides the best tissue for testing teratogenic fetuses. A humoral immune response mounted by the fetus can clear SBV from the fetus during gestation; consequently, SBV antibody testing of fetal heart blood or dam blood should be combined with RT-PCR testing of brainstem tissue for confirmation of SBV infection.

**NECROSYP FINDINGS**

The primary lesions with Akabane, Cache Valley, and Schmallenberg infections in the fetus are a necrotizing nonsuppurative encephalomyelitis and polymyositis. In calves and lambs with arthrogryposis, there is severe muscle atrophy, fixation of joints by tendon contracture, and normal articular surfaces. The joints are easily released by cutting the surrounding tendons. Histologically, there may be almost complete absence of ventral horn cells in the spinal cord. This lesion may be localized to one segment of the cord, and viral antigen may be demonstrated via immunohistochemistry.

In calves and lambs with hydranencephaly, the cerebral hemispheres are completely absent, and the vacant space is filled with fluid enclosed by the normal meninges. In a few cases the lesions will be limited to porencephaly. In most, the brainstem and cerebellum lack development, but diminution of their size may be recorded.

**Samples for Confirmation of Diagnosis**

- **Virology**—2 mL fetal heart blood and maternal serum for serology performed using ELISA
- **Histology**—brain, spinal cord, muscle (LM, IHC)

**DIFFERENTIAL DIAGNOSIS**

Akabane virus disease in calves, Cache Valley virus disease in lambs and kids, and Schmallenberg virus disease in calves, lambs, and kids, because they are manifested epidemiologically and are well-defined and easily recognizable entities. Differentials include the following:

- Lupine-induced arthrogryposis in calves
- Manganese deficiency in calves
- Heritable forms of arthrogryposis and/or micrencephaly
- Fetal infection with bluetongue virus, Rift Valley fever virus, or pestivirus
- Cattle in Japan may also produce hydranencephalic calves, which are recumbent, opisthotonic, and unable to suckle at birth, when infected during pregnancy by the Chuan virus. The virus, a member of the Polymavirus subgroup of orbiviruses, is transmitted by Culicoides oxystoma.

In Africa, infection with flaviviruses, including West Nile, Banzi, and ARS189, also causes abortion, stillbirth, and congenital brain malformations.

**TREATMENT AND CONTROL**

No treatment is contemplated because affected calves, lambs, and kids are not viable and cannot behumanely kept alive.

Vector control is not possible with current knowledge, and vaccination provides the most effective method of control.

Killed vaccines for Akabane virus have proved very effective against natural exposure and are available in Japan and Australia. Japanese data suggest vaccines should include genogroup Ia strains because these strains have a stronger neuroviruclence, and vaccine failures have been attributed to antigenic variation among Akabane virus strains. Vaccination requires two inoculations before pregnancy and an annual booster. Maternally derived antibodies against Akabane virus appear to last 4 to 5 months in Colostrum-fed calves, and they last slightly longer in beef calves than dairy calves, possibly as a result of a higher colostral titer in beef calf colostrum as a result of smaller colostral volumes. The economics of annual vaccination against Akabane virus is dictated by the risk of disease in regions subject to periodic outbreaks of disease.
A number of European countries, including Germany, France, and the Netherlands, made it mandatory to report the birth of malformed lambs, kids, and calves on farms seropositive for SBV. The numbers of abnormal lambs, kids, and calves born decreased in 2013 and 2014, most likely because of the development of herd immunity and high seroprevalence. Reemergence and spread of SBV within Europe is considered likely.

**REFERENCES**

In Brahman cattle, there is a common mutation affecting many Australian Brahman and a less common one affecting descendants of one imported bull. In addition, a third mutation is associated with significantly reduced α-glucosidase activity, but not sufficient to cause clinical disease in the homozygous state.

Clinical signs include poor growth, muscle weakness, incoordination of gait, and difficulty in rising. The animals become permanently recumbent. The disease is identified as a lysosomal storage disease, with lesions present in skeletal and cardiac muscle and central nervous tissue. During the course of the disease there is progressive muscular damage and acute degeneration of muscle fibers in the terminal stage. Affected Brahman calves die at 8 to 9 months of age and British breed cattle at over 1 year. Only histopathological lesions are evident and include extensive vacuolation and accumulations of granular material in affected tissues. Among the biochemical lesions are greatly diminished α-glucosidase activity in liver and muscle and a correspondingly high level of glycogen. Animals in affected herds are divisible into normal heterozygotes and homozygotes on the basis of α-1,4-glucosidase activity in lymphocytes or in muscle, especially the semitendinosus muscle.

Genotyping methods using hair root and blood samples to test Shorthorn cattle for generalized glycogenosis are available, and PCR assays have been developed to genotype Brahman cattle for loss-of-function alleles within the acidic α-glucosidase gene.

**GLYCOGEN STORAGE DISEASE TYPE V (MUSCLE GLYCOGEN PHOSPHORYLASE DEFICIENCY)**

Glycogen storage disease Type V (akin to McArdle's disease in humans) has been recorded in Charolais cattle in North America and Merino sheep in Australia. Type V is inherited as an autosomal-recessive trait, and the mutation in sheep has been identified as an adenine-for-guanine substitution at the intron 19 splice site, with subsequent lack of myophosphorylase activity. There is mildly elevated muscle glycogen concentration and elevated serum creatine and aspartate aminotransferase activity. Severely affected animals can develop rhabdomyolysis, which may be accompanied by myoglobinuria.

In Charolais cattle, glycogen storage disease type V is usually seen in calves at several weeks or months of age and is associated with exercise intolerance or reduced capacity for exercise. Calves lag behind their dam or herd and may become temporarily recumbent for several minutes; with continued exercise there are further periods of collapse and recumbency, which can become prolonged. Not all homozygous animals are clinically affected if they are allowed to "pace their exercise," and some animals have been known to breed despite muscle weakness.

The disease in Merino sheep is associated with exercise intolerance and increased concentrations of glycogen in muscle. A PCR restriction fragment length polymorphism test has been used to identify heterozygous individuals in a Charolais herd in New Zealand that were otherwise normal. Using a similar test, a Blode d'Aquitaine crossbred calf with a double-muscled phenotype and suspected of having myophosphorylase deficiency based on clinical findings of brown-colored transparent urine after exercise, pain, and elevated creatine kinase was considered negative. The gene maps to chromosome 29.

**INHERITED DIAPHRAGMATIC MUSCLE DYSTROPHY**

Inherited diaphragmatic muscle dystrophy is an inherited defect in diaphragmatic muscle of Meuse–Rhine–Yssel and Holstein–Friesian cattle appearing in adults and characterized by anorexia, decreased rumination, and eructation leading to recurrent bloat, dyspnea, abdominal respiration, nostril dilatation, and death from asphyxia after a course of several weeks. The disease is a result of a mutation involving one of the genes for heat shock protein 70 (HSP70), resulting in markedly reduced HSP70 concentrations in muscle of affected animals. Loss of HSP70 function causes accumulation of glycogen phosphorylase enzyme protein in muscle. Necropsy lesions comprise degenerative changes in diaphragmatic and thoracic muscles.

**REFERENCES**

**BOVINE FAMILIAL DEGENERATIVE NEUROMUSCULAR DISEASE**

Bovine familial degenerative neuromuscular disease has been reported as occurring in Gelbvieh cattle in several separate beef herds in the United States. Affected animals are 4 to 20 months of age, and the case-fatality rate is 100%. Clinical findings include ataxia, weakness, and terminal recumbency. Gross and histologic muscle lesions were indicative of nutritional muscular dystrophy with no myocardial lesions. Acute to chronic lesions in most large skeletal muscle groups consist of degeneration, necrosis, regeneration, fibrosis, and atrophy. Fibrinoid necrosis of arterioles is a common feature in multiple tissues. Lesions in the spinal cord white matter and peripheral nerves consisted of degeneration of the dorsal columns and axons, respectively. Chronic
interstitial nephritis with fibrosis, hyaline droplet change, and tubular epithelial vacuolar change were most severe in older calves. Vitamin E levels were abnormally low in most affected calves. Pedigree analysis found a common ancestry for all but one of the affected calves. It is hypothesized that a hereditary metabolic defect, possibly involving antioxidant metabolism, may be the causative factor.

INHERITED UMBILICAL HERNIA

Umbilical hernias in cattle have been considered to be inherited defects for many years, but the evidence is uncertain.

Umbilical hernias are commonly identified in dairy heifers. In 18 commercial dairy herds in New York, 15% of heifer calves had umbilical hernias during the first 3 months of age. The economic costs of umbilical hernias include the cost of medical and surgical treatment and the loss in value for breeding animals.

It has been generally accepted that umbilical hernias may be inherited in a dominant or recessive mode. Some studies have found the risk of hernias was higher in some breeds, with the incidence being much higher in Holstein cattle than other breeds such as Angus, Ayrshire, Brown Swiss, Charolais, Guernsey, Hereford, Jersey, and Shorthorn. However, aspects other than genetic factors may be important. For example, many veterinarians have observed that umbilical infections commonly lead to umbilical hernia by slowing closure of the umbilicus. It is unlikely that the responsible genes are sex-linked, in spite of the apparent greater incidence in females. Umbilical hernias in Holstein-Friesian cattle can also be conditioned by a dominant character with incomplete penetrance or be caused by environmental factors. In a case-control study to determine risk factors associated with identification of an umbilical hernia during the first 2 months after birth in Holstein heifers, the sire and umbilical infection were associated with risk of a hernia. Heifers born to sires with 3 progeny with an umbilical hernia were 2.31 times as likely to develop a hernia as were heifers born to sires with 2 progeny with an umbilical hernia. Heifers with umbilical infection were 5.65 times as likely to develop a hernia as were heifers without umbilical infection. Attributable proportion analysis found that the frequency of umbilical hernias in Holstein heifers with umbilical infection would have been reduced by 82% if umbilical infection had been prevented.

The risk factors for congenital umbilical hernias in German Fleckvieh calves offered for sale at livestock markets were examined. An umbilical hernia was defined as a palpable opening in the abdominal wall of the umbilical region greater than 1.5 cm, even if no hernia had developed. Inflammation, abscesses, or fistulae were excluded. Data from 53,105 calves were collected from 77 livestock markets over a 2-year period. The overall incidence of congenital hernia was 1.8%. The analyses found significant effects for sex of calf, birth type, age of calf at examination, market place and date, sire line, sire, and frequency of affected herdmate calves in male calves. The incidence was 2.2% in males and 1.5% in females. The calves varied from 3 to 8 weeks of age. The diameter of hernial openings was between 1.5 and 9 cm, with 47% of affected calves with a hernia measuring greater than 3 cm. A significantly higher incidence occurred in twin or triplet calves. Shorter gestation periods increased the risk of hernias linearly by a factor of 1.3% for 10 days. There were differences in the incidence of hernias according to sire lines, but the heritability estimates were low, varying from $h = 0.04$ ($>100$ progeny) or $h = 0.05$ ($>25$ or $50$ progeny). However, analysis of the data found no evidence for a monogenic autosomal-recessive inheritance. The analyses indicated that the incidence of congenital umbilical hernia observed could not be explained by one autosomal-recessive gene locus; it seems much more likely that more than one gene locus is involved, or a mixed multifactorial monogenic mode of inheritance may be the underlying genetic mechanism. It is suggested that the incidence of congenital umbilical hernias could be reduced if all breeding bulls are examined as calves and a veterinary certificate confirms a closed umbilical ring.

Breeders should be aware of the implications of congenital hernias, and, thus, congenital hernia should get more attention in the selection process of young sires.

Breeding studies and genotyping using the Canadian Holstein bull Glenhaption Enhancer have provided evidence that Enhancer is the carrier of a major dominant or codominant gene with partial penetrance for umbilical hernia. Five sons of Enhancer produced progeny with greater than 10% frequency of umbilical hernia, whereas the progeny of three sons had less than 3% frequency umbilical hernia. Genotyping of grand-progeny found significant differences in paternal allele frequencies between the affected and unaffected progeny groups for a marker BMS1591 on bovine chromosome 8(BTA8). The umbilical hernia-associated paternal allele originated from Enhancer.

MYOFIBER HYPERPLASIA (DOUBLE MUSCLING, DOPPELENDER, CULARD)

EPIDEMIOLOGY

Myofiber hyperplasia is an inherited condition characterized by an increased bulk of skeletal muscles as a result of the presence of a greater-than-normal number of muscle fibers that occurs in Charolais, Belgian Blue (Fig. 15-15), Piedmont, and South Devon breeds. The condition is recorded only rarely in sheep (Texel breed). 1 Pietrain pigs (see following discussion) exhibit many of the characteristics of double-muscled cattle, including large muscle mass and susceptibility to stress.

The condition in Belgian Blue cattle is attributable to a mutation in the MSTN gene that regulates myostatin production. 1-3 Inhibition of myostatin, through a loss-of-function mutation, results in increases in muscle fiber number and muscle mass. The disease in Belgian Blue cattle, and presumably in other breeds of cattle and sheep,

Fig. 15-15 Myofiber hyperplasia in a Belgian Blue cow.
is transmitted as an autosomal-recessive characteristic. A similar mutation in Thoroughbred horses is associated with superior sprint (<1600 m) racing performance. The mutation has been induced experimentally in Meishan pigs.

The mutation of MSTN was “fixed” in the Belgian Blue breed in the 1990s as a result of strong selection pressure for the double-muscle phenotype. Subsequent continued selection pressure has resulted in increases in frequency of other haplotypes favoring increased lean muscle mass, resulting in a polygenic basis for the current phenotype. Selection of the phenotype is currently limited because of the occurrence of crooked-tail syndrome (see section on Inherited Taillessness and Tail Deformity later in this chapter) in animals homozygous for the MRC2 gene, which encodes protein Endo180. Animals heterozygous for the MRC2 mutation do not have crooked-tail syndrome and have enhanced muscularity.

CLINICAL FINDINGS
Severely affected cattle show a marked increase in muscle mass most readily observed in the hindquarters, loin, and shoulder; an increase in the muscle :bone ratio; and a decrease in body fat. Affected calves demonstrate above-average weight gains during the first year of life if well fed and managed, although mature size is somewhat reduced. Well-marked grooves along the intramuscular septa in the hindquarters are a distinguishing feature, as is an apparent forward positioning of the tail head. Macroglossia, prognathism, and a tendency toward muscular dystrophy and rickets have been observed in affected calves. Electrocadiographic abnormalities have been reported. The condition often gives rise to dystocia and the need for frequent caesarian section to deliver viable calves. There is also a very high incidence of Elso heel in affected cattle, and this interferes greatly with their economic value. Other associated defects are brachygnathia, deviation of the incisor arch, and, in Belgian Blue and White cattle, greater susceptibility than normal to laryngitis and bronchopneumonia.

CLINICAL PATHOLOGY
Blood lactate is increased, as is susceptibility to stress. These findings are interpreted as being indicators of cell-membrane fragility, which is also manifested by fragility of the erythrocytes.

NECROPSY FINDINGS
The skin is thinner than normal, and the muscle mass is characterized by a disproportionate number of glycolytic anaerobic fibers.

REFERENCES
and relaxation are determined by Ca$^{2+}$ interaction with contractile proteins. Ca$^{2+}$ is normally stored in the lumen of the sarcoplasmic reticulum, and its release into the cellular cytoplasm induces muscle contraction. At the end of a contraction cycle, SERCA1 proteins pump excessive Ca$^{2+}$ ions back from the cytoplasm into the sarcoplasmic reticulum to initiate relaxation. Impaired back from the cytoplasm into the sarcoplasmic reticulum induces muscle contracture. At the end of a contraction cycle, SERCA1 proteins pump excessive Ca$^{2+}$ ions back from the cytoplasm into the sarcoplasmic reticulum to initiate relaxation. Impaired function of SERCA1 delays the removal of Ca$^{2+}$ from the cytosol of muscle fibers, thereby prolonging the contractile phase.3

**CLINICAL FINDINGS**

Although PMT and CMD1 are caused by the same gene defect, the clinical presentation of both conditions differs markedly.

**Congenital Muscular Dystonia Type 1 (CMD1)**

CMD1 is a fatal congenital and nonprogressive condition of Belgian Blue calves.7 The disease is characterized by exercise-induced pronounced episodes of generalized muscle contractures. During such episodes the affected calf has stiffened limbs and is unable to move or may even flip over with the extremities extended. Impaired swallowing has also been reported, and affected calves usually die in the first weeks of life as a result of respiratory complications.7

**Pseudomyotonia (PMT)**

PMT in cattle is a congenital and nonprogressive disease characterized by a generally increased muscle tone and exercise induced episodic contractures. Affected animals are reported to have a stiff or clumsy gait from birth on, and forcing them to move faster than at their own pace will trigger an episode of transient muscle contracture lasting from 20 seconds to over 1 minute. During this episode the animal is unable to move as a result of rigidity of the limbs. It either adopts a saw-horse type posture or may even flip over with all of the limbs extended. After a variable time period lasting from a few seconds to over a minute, the muscle contracture resolves progressively and the animal returns to its normal behavior. Although affected animals are often thought to have a neurologic affliction, the condition is purely a muscular disorder and is not associated with any neurologic deficiencies. In contrast to CMD1, animals with PMT can reach adult age.1

**CLINICAL PATHOLOGY**

Clinically, the condition is indistinguishable from myotonia, a chloride channel disorder, occurring incidentally in cattle as consequence of a spontaneous mutation in the CICN1 gene (see also “Myotonia of Goats”). Percussing large muscle bellies either with the fingers or a percussion hammer will fail to produce local muscle fasciculation (per- cussion myotonia) in calves with PMT or CMD1, which would be characteristic for myotonia. Electromyographic examination is unremarkable, which also allows for differentiation of the condition from myotonia.1,3

**TREATMENT**

There is currently no specific treatment available.

**NECROPSY FINDINGS**

Necropsy examination has been not reported to yield remarkable findings.

**CONTROL**

With the condition being inherited in an autosomal-recessive manner, it has been recommended to test parents of a calf confirmed with PMT or CMD1 for the presence of the gene defect. Parent animals recessively carrying the gene defect are clinically healthy but should not be used for breeding. For populations with high prevalence of the gene defect, it is advisable to systematically check breeding bulls for the presence of the mutations before using their semen for breeding.6

**REFERENCES**

**MYOTONIA OF GOATS (FAINTING GOATS)**

**SYNOPSIS**

**ETIOLOGY**

Myotonia of goats describes an inherited condition that is characterized by an abnor- mal delay in muscle relaxation following voluntary forceful muscle contraction.1 The underlying cause is a structural and functional defect of the skeletal muscle chloride channel 1 (CIC1) that is essential to restore and maintain the membrane potential of muscle cells at the resting level. A missense mutation of the CICN1 gene encoding the skeletal muscle CIC1 in so-called fainting goats has been identified and has been associated with decreased muscle chloride conductance resulting from a decreased number of functional chloride channels on muscle cell membranes.2

Anecdotal evidence suggests that the myotonic goat phenotype is transmitted as an autosomal-dominant trait, although many herds have been inbred, resulting in clinical presentation reminiscent of human recessive generalized myotonia (or Becker myotonia) with recessive inheritance.1

Historically the fainting goats played an important role in the process of unraveling the etiology and pathophysiology of congenital myotonia, a condition also affecting humans and other species.3

**EPIDEMIOLOGY**

**Occurrence**

Myotonia in goats was first reported in the 1880s in Tennessee, United States, where several does and one buck with signs of nervousness and stiffness appear to have been introduced by a transient farm worker.1 Since then, the progeny of these animals have become established in the area. These goats, which are now a recognized breed, the fainting goat, became popular in the region as shepherds used them to protect their flocks from predators. During a predator attack, the...
fainting goat would become startled and develop a characteristic episode of muscle stiffness, making it an easy prey, while the rest of the flock would be able to make an escape.

Currently there are two strains of this breed, which is indigenous to the United States. The original strain in Tennessee and the eastern part of the United States consists of smaller animals, whereas fainting goats found in and around Texas have been selectively bred for the meat market and are larger and heavy rumped, with a deep chest. The Livestock Breed Conservancy has this goat breed listed as a conservation priority livestock breed, with an estimated world population below 10,000 head.1

**Economic Importance**
Myotonic goats are considered a rare breed. Although historically their main purpose appears to have been to serve as prey animals to protect flocks from predators, this use has fallen out of practice. Today the main purposes are meat production and amusement. Myotonia is generally accompanied by muscle fiber hypertrophy, yielding greater muscle mass, less body fat, and higher bone-to-meat ratio than other breeds. Frequently this breed is kept as pet for its fainting spells for the owners’ amusement, which has led to ethical concerns about breeding animals with this gene defect.

**PATHOGENESIS**
The missense mutation in the ClCN1 gene results in the transcription into a faulty chloride channel 1 protein that reduces the sarcolemmal chloride conductance. With normal chloride conductance across muscular cell membranes, chloride moves in and out of the cell until the intracellular concentration is adjusted to set the chloride equilibrium potential equal to the resting potential. The function of chloride is to rapidly return the membrane potential of the contracted and thus depolarized cell to the resting membrane potential, thereby allowing muscle relaxation. A reduced number of functional chloride channels on the sarcolemmal membrane reduces the velocity with which the membrane potential can be returned to the resting level, which has two important consequences: (1) a lower electrical stimulus is required to trigger an action potential, resulting in increased excitability of the muscle cell; and (2) after initial depolarization, the membrane potential very slowly returns to a normal resting membrane potential. Until the resting membrane potential is reached, the actual membrane potential is closer to the threshold voltage needed to trigger a new action potential, which can result in spontaneous action potentials that are not triggered by neuromuscular transmission. Such autonomous action potentials will cause persistent muscle contraction and delayed muscle relaxation after an initial vol-

**CLINICAL FINDINGS**
The congenital condition that is characterized by a delay in muscle relaxation following an initial voluntary contraction is present from birth and is nonprogressive. Although affected goats are referred to as fainting goats, the condition is a purely muscular disorder and not associated with any neurologic deficits. The severity can vary from very mild to severe, and it appears that goats are able to adjust to the condition with age. Myotonia is not associated with pain.

A typical presentation is a slightly to moderately increased resting muscle tone that may result in a clumsy or stiff gait in animals with severe myotonia. Myotonic episodes and muscular stiffness can be triggered by startling the animal and thereby inducing a forceful initial movement. Because of delayed muscle relaxation, initially contracted muscles remain tensed for a period of between 10 seconds and 1 minute or longer and relax progressively thereafter. During this prolonged phase of muscle contraction, animals may either remain in a sawhorse-type position or may flip over with extended, stiffened limbs. Once muscle contraction resolves, the animal returns to normal attitude and behavior.

**CLINICAL PATHOLOGY**
The presentation is characteristic, with animals being affected from birth by inducible myotonic episodes. Clinically the diagnosis can be supported by percuting large muscle bellies either with the fingers or a percussion hammer. In myotonic animals, muscle percussion triggers local muscle fasciculation (percussion myotonia) that lingers for several seconds. Electromyographic examination reveals increased insertional activity when inserting myography needles into muscle tissue and continued high-frequency discharges that outlast normal motor unit responses by several seconds.

To confirm the diagnosis, DNA analysis to confirm the presence of mutation in the ClCN1 gene is required.9

**NECROPSY FINDINGS**
Necropsy examination is not usually undertaken for diagnostic purposes.

**REFERENCES**

**MYOTONIA CONGENITA AND MYOTONIC DYSTROPHY**
Myotonia is the prolonged contraction of muscle as a result of delayed relaxation. It can be present soon after birth or develop as a progressive disease.

The congenital form in horses (New Forest ponies), goats, and Murrah buffalo is an inherited disorder of muscle membrane hyperexcitability caused by mutations in the voltage-gated chloride channel gene ClCN1. The mutation reduces sarcolemmal chloride conductance and delays relaxation of the muscle.1,2 It is transmitted as an autosomal-recessive trait in ponies.1 The disease is evident as generalised myotonia evident soon after birth. The disease is not progressive, but there is not treatment. Control is based on breeding programs.

The disease in horses myotonia dystrophia is evident as increased muscle tone, increased muscle bulk or muscle atrophy, stiffed gait, and weakness.3 Electromyographic examination reveals the classic myotonic discharges. Affected horses can have testicular atrophy and cataracts. The disease is progressive. There are no characteristic changes in blood or serum. Muscle biopsy demonstrates dystrophic changes, with variations in fiber size and fiber-type grouping. There is no effective treatment, and control is through avoidance of breeding of affected animals.

**REFERENCES**

**RECURRENT EXERTIONAL RHABDOMYOLYSIS IN THOROUGHBRED AND STANDARDBRED HORSES**

**ETIOLOGY**
Recurrent exertional rhabdomyolysis is a recognized syndrome in Thoroughbred, Standardbred, and Arabian racehorses. A genetic basis is considered likely, with heritability of 0.42,4 but has not been demonstrated. Genome-wide scans and linkage analyses map candidate genes to the genomic region between UCDEQ41 and TKY499 on ECA12 (Equus caballus chromosome 12) or regions on ECA16 or ECA 20.5 The differences between the two studies, with one mapping to ECA166 and the other to ECA12 and ECA20,7 might be attributable to the
study of different populations of horses (North America vs. Japan), phenotyping (disease classification), or laboratory techniques. The RYR1, CACNA1S, and ATP2A1 genes are not linked to recurrent exertional rhabdomyolysis in Thoroughbreds, nor do affected Standardbred horses have the GSY1 mutation identified as a cause of polysaccharide storage myopathy in Quarter horses, draft horses, and other breeds. Mutations in genes expressing monocarboxylate transporter 1 and CD147 are not associated with the disease.

Recurrent exertional rhabdomyolysis in Thoroughbreds is likely to be a complex genetic disease resulting from one or more genes having a major effect, with expression affected by modifying genes, environment, or sex.2,6

**EPIDEMIOLOGY**

Interpretation of reports of prevalence and risk factors for exertional rhabdomyolysis are imprecise because of difficulties in distinguishing the disease from other causes of rhabdomyolysis, including the sporadic disease. The incidence or 1-year period prevalence of exertional rhabdomyolysis is as follows: 4.9% in Thoroughbred racehorses in the United States, Australia, and Great Britain; 6.1% in National Hunt Thoroughbreds in Great Britain; and 4% to 5% in 2- to 3-year-old Thoroughbreds in the United Kingdom.1 The annual incidence in Standardbred racehorses in Sweden is 6.4 (95% CI 4.6% to 8.2%) per 100 horses.1 Annual incidence in 22 Standardbred training yards in Sweden ranged from 1.7 to 20 cases per 100 horses.1

Risk factors for recurrent exertional rhabdomyolysis include exercise and sex. Female racehorses are 3 times more likely to have episodes of exertional rhabdomyolysis than are male (intact or castrated) racehorses, and young female Thoroughbreds are at greatest risk. Among 2- to 4-year-old Thoroughbreds in the United Kingdom, 76% to 78% of occurrences of “tying-up” are in females, and female Standardbreds in Sweden are 7 times more likely (95% CI 2.1 to 23.4) to be affected by the disease than are males.1 Among National Hunt horses in Great Britain, females are 24 times as likely to have an episode of the disease as are males. Thoroughbred racehorses and Standardbred horses (odds ration [OR] 7.9, 95% CI 2.3 to 27)1, but not National Hunt horses, with a nervous or “flighty” temperament are more likely to experience episodes of the disease.1

The disease occurs repeatedly in 74% of affected Thoroughbred racehorses in Great Britain and in 20% of affected polo ponies.

The disease is of considerable economic impact because of its frequent occurrence in athletic horses, its recurrent nature, and the need to rest affected horses.8 On average, affected Thoroughbred racehorses cannot train for 6 days, and Standardbreds for 7 days, after an episode,4,8 and approximately two-thirds of affected horses are unable to race because of the disease. The effect of the loss of training days for each episode is magnified because of the recurrent nature of the disease in a large proportion of affected horses. Approximately 6% of the wastage of Thoroughbred racehorses in Australia is attributable to exertional rhabdomyolysis.

Interestingly, Standardbred horses in the United Kingdom with recurrent exertional rhabdomyolysis have enhanced performance.4

**PATHOGENESIS**

The cellular defect has not been identified and fully explicated. Muscle from affected horses has abnormal contraction and relaxation kinetics and is hypersensitive to exposure to caffeine in vitro, but connection with development of the disease is unclear. Affected French Trotters have a characteristic micro-RNA profile in muscle, although this might represent a response to muscle damage rather than the mi-RNA’s involvement in development of the disease.9

The disease is attributable to dysfunction and death of myocytes with subsequent release of cellular constituents, including the enzymes creatine kinase, aspartate aminotransferase, and carbonic anhydrase, and myoglobin. The proximate cause of myocyte death is uncertain, but it is not related to accumulation of lactic acid.

Cell death is likely linked to abnormal accumulation of calcium in intracellular fluids secondary to deranged energy and/or membrane function. Necrosis of myocytes causes pain and inflammation in the muscle, with infiltration of inflammatory cells. Healing and regeneration of myocytes occurs over a period of weeks in the absence of further episodes of myonecrosis.

Release of cellular constituents results in electrolyte abnormalities, primarily a hypochloremic metabolic alkalosis, a systemic inflammatory response, and pigmenturia. Severely affected horses can have a metabolic acidosis. Myoglobin, and possibly other cell constituents, is nephrotoxic, and acute renal failure can develop as a result of myoglobinuric nephrosis. Pain and loss of muscle function cause a stilted, short-stepping gait.

**CLINICAL FINDINGS**

The clinical findings are variable and range from poor performance through classic signs of muscle pain, stiffness, and reluctance to move, to recumbency and death, although the latter are rare with recurrent exertional rhabdomyolysis. Most affected horses have more than one episode of the disease each year while in training, and some can have numerous episodes (up to 20).1,8

The most common presentation is of a horse that does not perform to expectation and displays a stiff or short-stepping gait that can be mistaken for lower leg lameness. The horse might be reluctant to move when placed in its stall, be apprehensive and anorexic, paw, and frequently shift its weight. More severely affected horses can be unable to continue to exercise, have hard and painful muscles (usually glutal muscles), sweat excessively, tremble or have widespread muscle fasciculations, be apprehensive, refuse to walk, and have elevated heart and respiratory rates. Affected horses can be hyperthermic, especially soon after exercise. Signs consistent with abdominal pain are present in many severely affected horses. Deep-red urine (myoglobinuria) occurs but is not a consistent finding. Severely affected horses are often recumbent.

Among affected Standardbred horses, clinical signs are evident in 98% of horses within 1 hour of exercise. Clinical signs include stiffness in all cases (44), sweating (86%), pain or evident distress (43%), swollen or firm gluteal muscles (23%), and recumbency (2%).4

**CLINICAL PATHOLOGY**

Mildly affected or apparently nonaffected horses have moderate increases in serum creatine kinase (CK) (20,000 to 50,000 IU/L), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) activity. Severely affected horses have large increases in CK (>100,000 IU/L) and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5 to 6 and 24 hours after exercise, respectively, and in the absence of further muscle damage, serum AST might not return to normal levels for 7 to 10 days. The half-life of CK activity in serum is approximately 2 hours, and in the absence of continuing muscle damage, serum CK declines rapidly. The persistence of increased AST activity, compared with CK, is useful in identifying affected horses days or weeks after the episode.4

Serum myoglobin concentrations increase markedly during exercise in affected horses and decline within 24 to 48 hours. Serum carbonic anhydrase III activity is increased in horses with exertional rhabdomyolysis.8

Severely affected horses are often hypotonatremic (<130 mEq/L), hyperkalemic (>5.5 mEq/L), hypochloremic (<90 mEq/L), azotemic (increased serum urea nitrogen and creatinine concentrations), and acidotic or alkalotic. Hemoconcentration (hematocrit >50%, 0.5 L/L) and increased serum total protein concentration (>80 g/L) indicative of dehydration are common. Serum bicarbonate concentration can be falsely markedly elevated in animals with severe rhabdomyolysis because of cellular constituents released from damaged muscle that interfere with the analytical method when automated clinical chemistry analyzers are used. Myoglobinuria is detectable either grossly or on chemical analysis and should be differentiated from hemoglobinuria or hematuria.
Measurement of urinary excretion of electrolytes, although popular in the past, is of no use in diagnosing, treating, or preventing exertional rhabdomyolysis.

Muscle biopsy during the acute or convalescent stages reveals myonecrosis of type II (fast-twitch, oxidative) fibers, mild myositis, and fibrosis.

Necropsy findings

Horses dying of exertional rhabdomyolysis have widespread degeneration of striated muscle, principally the muscles of exertion, but often involving the diaphragm and heart. Affected muscles tend to be dark and swollen but may have a pale, streaked appearance. The kidneys are swollen and have dark-brown medullary streaks. Dark-brown urine is present in the bladder. Histologic examination reveals widespread necrosis and hyaline degeneration of predominantly type II (fast-twitch, oxidative) fibers. In horses with recurrent disease, there may be evidence of myofiber regeneration. Myoglobinuric nephrosis is present in severely affected horses.

Samples for Postmortem Confirmation of Diagnosis
- Formalin-fixed kidney and affected muscle for light microscopic examination (LM)

Diagnostic Confirmation

Biochemical confirmation of muscle damage by demonstration of increased serum CK or AST activity, in conjunction with appropriate clinical signs, provides the diagnosis.

Differential Diagnosis

- Muscle cramping induced by ear tick (Otodius megnini)
- Ionophore intoxication (monensin, lasalocid, salinomycin, narasin, maduramicin)
- Infection by Anaplasma phagocytophilum
- White snake root (Eupatorium rugosum) or rayless goldenrod (Isocoma pluriflora)
- Laminitis
- Colic
- Pleuritis
- Aorto-iliac thrombosis

Treatment and Control

Treatment of Acute Disease
- Nonsteroidal antiinflammatory drugs—phenylbutazone (2.2 to 4.4 mg/kg IV or PO q12–24h) or ketoprofen (2.2 mg/kg IV every 12 h) (R-1)
- Rest (R-1)
- Fluid therapy—as needed (R-1)

The treatment chosen depends on the severity of the disease. The general principles are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia, and are the same as for all acute myopathies with rhabdomyolysis.

Mildly affected horses (heart rate < 60 bpm, normal rectal temperature and respiratory rate, no dehydration) may be treated with rest and phenylbutazone (2.2 mg/kg, orally or IV every 12 hours for 2 to 4 days). Horses should be given mild exercise with incremental increases in workload as soon as they no longer have signs of muscle pain. Access to water should be unrestricted.

Severely affected horses (heart rate > 60 bpm, rectal temperature > 39°C [102°F], 8% to 10% dehydrated, reluctant or unable to walk) should not be exercised, including walking back to the stable, unless it is unavoidable. Isotonic, polyionic fluids, such as lactated Ringer’s solution, should be administered IV to severely affected horses to correct any hypovolemia and to ensure a mild diuresis to prevent myoglobinuric nephropathy. Less severely affected horses can be treated by administration of fluids by nasogastric intubation (4 to 6 L every 2 to 3 hours). Although it has been recommended that urine should be alkalized by administration of mannitol and sodium bicarbonate (1.3% solution IV, 50 to 100 g of sodium bicarbonate orally every 12 hours) to minimize the nephrotoxicity of myoglobin, this therapy is not effective in humans at risk of myoglobinuric nephrosis. Affected horses should not be given diuretics (e.g., furosemide) except if they are anuric or oliguric after correction of hypovolemia.

Phenylbutazone (2.2 to 4.4 mg/kg, IV or orally, every 12 to 24 hours), flunixin meglumine (1 mg/kg IV every 8 hours), or ketoprofen (2.2 mg/kg IV every 12 hours) should be given to provide analgesia. Mild sedation (acepromazine 0.02 to 0.04 mg/kg IM, or xylazine, 0.1 mg/kg IM, both with butorphanol, 0.01 to 0.02 mg/kg) might decrease muscle pain and anxiety. Tranquilizers with vasodialatory activity, such as acetylpromazine (acepromazine), should only be given to horses that are well hydrated. Muscle relaxants, such as methocarbamol, are often used but have no demonstrated efficacy.

Recumbent horses should be deeply bedded and repositioned by rolling every 2 to 4 hours. Severely affected horses should not be forced to stand.

CONTROL

Although the cause has not been identified, a number of preventive measures are used, including the following: ensuring consistency of exercise (i.e., every day); dietary interventions to provide a high-fat, low-soluble-carbohydrate diet, with reduction of the amount of soluble carbohydrate in the diet on days when the horse will not exercise; and administration of dantrolene sodium.

Despite lack of clear evidence for a role for vitamin E or selenium deficiency in recurrent exertional rhabdomyolysis, horses are often supplemented with 1 IU/kg vitamin E and 2.5 mg/kg selenium daily in the feed. Care should be taken not to induce selenium toxicity.

Sodium bicarbonate (up to 0.5 to 1.0 g/kg BW daily in the ration) and other electrolytes are often added to the feed of affected horses, but their efficacy is not documented. Phenytoin is administered at a dose rate of 6 to 8 mg/kg, orally, every 12 hours, and the dose is adjusted depending on the degree of sedation produced (a reduced dose should be used if the horse becomes sedated) or lack of effect on serum CK or AST activity. Phenytoin can be administered to horses for months, although its efficacy has not been demonstrated. Dimethylglycine, alrenogest, and progesterone are all used on occasion in horses with recurrent rhabdomyolysis, but again without demonstrated efficacy.

The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of recurrent exertional rhabdomyolysis in Thoroughbred horses, and dietary modifications that reduce feeding of grain (oats) are common in Standardbred horses in Sweden (and likely elsewhere). Administration of dantrolene sodium (1 to 3 mg/kg, PO q24 h) has been advocated for prevention or amelioration of recurrent exertional rhabdomyolysis, and the pharmacokinetics of dantrolene in horses have been determined. Dantrolene reduces calcium efflux from the sarcoplasmic reticulum and is a muscle relaxant. Plasma concentrations are greatest when it is administered with feeding, and feed restriction for more than 4 hours before oral administration decreases gastrointestinal absorption of dantrolene. There is only relatively weak laboratory or field trial evidence of the efficacy of dantrolene in prevention of the disease.

POLYSACCHARIDE STORAGE MYOPATHY OF HORSES

Polysaccharide storage myopathy, a myopathy of principally Quarter horses and related breeds, but also occurring with high frequency in draft breeds, is characterized by excessive accumulations of amylase-resistant glycogen (evident as amylase-resistant polysaccharide on periodic acid–Schiff [PAS] staining) in muscle and signs of exertional rhabdomyolysis. One form of the disease is associated with a specific mutation in the GYS1 gene (polysaccharide storage myopathy 1 [PSSM1]) and another with an identical phenotype but without the same genetic abnormality (PSSM2).

ETIOLOGY

PSSM1 is the result of a single missense G-to-A gain-of-function mutation in the skeletal muscle glycogen synthase (GYS1) gene that results in a histidine (H) substitution for arginine (R) in the enzyme.1,2 The mutation is dominant, with both homozygotic (AA, both H alleles) and heterozygotic (GA, one H allele, one R allele) animals affected. Homozygotes for the H allele are more severely affected than are heterozygotes, as indicated by accumulation of amylase-resistant polysaccharide in muscle and elevated resting serum CK and AST activities.3 The mutation is conserved in the haplotype of many affected horse breeds, has been present in horses for over 1200 years, and is widely distributed among breeds of horses, with the mutation identified in over 30 breeds.4 The gene is well characterized in equids.1

The etiology of PSSM2 is not known, but it is not associated with the same mutation as PSSM1.

EPIDEMIOLOGY

A polysaccharide storage myopathy characterized by accumulation of polysaccharide in muscle was described in Quarter horses and other breeds and subsequently recognized as being either of amylase-resistant polysaccharide or amylase-sensitive polysaccharide. Approximately 48% of 831 muscle samples from horses with PSSM tested positive for the GYS1 mutation, with 16% of horses with amylase-sensitive polysaccharide accumulation having the H allele and 70% of horses with amylase-resistant having the allele. Of the 831 horses, 31 (3.7%) were homozygous for the H allele (gene AA), 379 (45.6%) were heterozygous (HR for enzyme, GA for gene), and 430 were homozygous normal (RR for enzyme, GG for gene). The presence of the mutated gene (heterozygous form) increases the risk of clinical exertional rhabdomyolysis by 7 times in Warmblood horses.5

The disease and mutation are recognized in many breeds, with the greatest frequency in Quarter horses and related breeds and draft breeds worldwide.5–7 Allele frequencies are available for PSSM in horses in the United States (Percheron, 0.346; Belgian, 0.242; Paint, 0.041; Quarter horse, 0.034; Appaloosa, 0.030; Morgan, 0.005; Shire, 0.005; Thoroughbred, 0.000) and Europe (South German Coldblood, 0.117; Saxon-Thuringian Coldblood, 0.068; Shire, 0.000; Hanoverian, 0.000).8 The GYS1 mutation was detected in 11 breeds, with a prevalence of genetic susceptibility to type 1 PSSM from 0.5% to 62.4%. The GYS1 mutation was not found in the sampled Thoroughbreds, Akhal-Teke, Connemaras, Clydesdales, Norwegian Fjords, Welsh Ponies, Icelandics, Schleswig Coldbloods, or Hanoverians, but failure to detect the mutation does not guarantee its absence from the breed, although it does imply a low prevalence.9

PSSM, based on examination of muscle biopsy from a convenience sample of 164 Quarter horses, occurs in 6% to 12% of overtly healthy Quarter horses in the United States.9 Allele frequencies for type 1 PSSM among Quarter horses in the United States range from 0.055 to 0.155, depending on the population sampled.10

The mutation, and disease, are common in Percheron and Belgian draft horses in Europe, and the disease is reported in Normandy Cob draft horses.11–13 Of a nonrandom selection of continental European draught horses belonging to 13 breeds, 62% (250 of 403) tested were found to carry the mutant allele.14 The highest percentages of GYS1-positive horses were found in the Belgian trekpaard (92%, 35 of 38 horses tested), Comtois (80%, 70 of 88), Netherlands trekpaard (74%, 17 of 23), Rheinisch-Deutsches kalbit (68%, 30 of 44), and Breton (64%, 32 of 51).15 There is genetic evidence of historical selection pressure in favor of the mutated genotype in Belgium draft horses, but not in American Quarter horses.16

The mutation has not been detected in purebred Thoroughbred, Standardbred, and Arabian horses.1,18 It appears that the GYS1 mutation arose in heavy (draft) breeds of horses in Europe over 1200 years ago, as indicated by its high frequency in European draft breeds, but not English draft breeds, and the lower prevalence of the mutation in lighter breeds.1 Light breeds with closely kept stud books that have prevented ingress of genes over centuries, such as Thoroughbreds and Standardbreds, do not carry the mutant gene.

Animal risk factors for exertional rhabdomyolysis include breed (as discussed previously) but not sex or age.11,19 Quarter horses that carry a mutation of the RYR1 (ryanodine) gene and the mutated GYS1 gene have more severe expression of the disease.20

Prolonged periods of rest or irregular exercise schedules are risk factors for development of exertional rhabdomyolysis associated with the disease.

PATHOGENESIS

Mutation of the GYS1 gene causes increased activity in muscle glycogen synthase activity without an increase in activity of glycogen branching enzyme.2 There is subsequent accumulation of amylase (diastase)-resistant polysaccharide (polymyocarid)—proglycogen and macroglycogen with fewer branching points and more straight chains—in skeletal muscle.21 The reason that accumulation of polysaccharide causes myopathy and exertional rhabdomyolysis is unclear. It does not appear to be related to availability of energy within the cell, although this is uncertain, and it could be related to physical damage caused by accumulation of polysaccharide in vacuoles within predominantly type 2A fibers of homozygous horses.

CLINICAL FINDINGS

The clinical findings are variable and range from sporadic to episodic exertional rhabdomyolysis of varying severity. Notably, 6% to 12% of overtly healthy (asymptomatic) Quarter horses in the United States have histologic evidence of the disease.22 The acute clinical syndrome does not vary importantly from that of other exertional rhabdomyolysis syndromes. Horses with PSSM1 do not have important cardiac abnormalities as part of their disease syndrome.23

Muscle biopsy reveals accumulation of amylase (diastase)-resistant polysaccharide (PAS-positive) inclusions in vacuoles in predominantly, but not exclusively, type 2A and type 2X fibers.2 Examination of muscle biopsies from candidate horses should be done with consideration of the risk of false-negative findings, especially if the amylase-resistant nature of the polysaccharide is not determined. Horses with PSSM2 will have excess accumulation of amylase-resistant polysaccharide but will not have the mutation in the GYS1 gene. PSSM is most accurately diagnosed in muscle biopsy specimens on the basis of appearance of amylase-resistant, abnormal polysaccharide, not amylase-sensitive glycogen, regardless of fixation technique.24
CLINICAL PATHOLOGY
Most Quarter horses and related breeds, but not draft breeds, with the GYS1 mutation have elevations in serum CK and AST at rest.1 Mildly affected or apparently nonaffected horses have moderate increases in serum CK, AST, and LDH activity after moderate exercise. Severely affected horses have large increases in CK and other muscle-derived enzymes. Serum CK and AST activities peak approximately 5 to 6 and 24 hours after exercise, respectively, and in the absence of further muscle damage, serum AST might not return to normal levels for 7 to 10 days.

NECROPSY FINDINGS
Gross lesions may vary depending on whether or not the horse died from severe rhabdomyolysis or was euthanized after being recumbent. Affected muscles may be pale pink or diffusely red-tinged, which can be mistaken for autolysis. Any of the large power muscle groups and the diaphragm can be affected. The kidneys may be swollen and dark red as a result of myoglobinuria. In chronic cases with repeated episodes, muscle atrophy may be marked, or the muscles may be of normal size but contain pale streaks where myofibers have been replaced by fat.

Microscopically, the presence of amylase-resistant, abnormal polysaccharide inclusions in the cytoplasm of type 2 myocytes is the most sensitive and specific diagnostic indicator for polysaccharide storage myopathy.23 Other lesions, such as fiber atrophy, internal nuclei, and fatty infiltration, may be present. Muscles most often affected include the semimembranosus, semitendinosus, gluteal, longissimus, and pectoral muscles and the diaphragm.24

Samples for Postmortem Confirmation of Diagnosis
Samples of semimembranosus, semitendinosus, gluteal, and diaphragmatic muscles for H & E and PAS stains are used for confirmation of the diagnosis. Frozen sections of biopsies are better suited for studying myopathies because many histopathologic features of skeletal muscle are obscured by formalin fixation.23

DIAGNOSTIC CONFIRMATION
Biochemical confirmation of muscle damage is achieved by demonstration of increased serum CK or AST activity in horses with compatible clinical signs. In breeds with known or strongly suspected genetic basis for PSSM1, gene testing for the GYS1 mutation provides evidence of the PSSM1. Confirmation is achieved by examination of a muscle biopsy (see Diagnostic Algorithm in Fig. 15-1). If the muscle biopsy demonstrates the presence of amylase-resistant polysaccharide and the horse is negative for the AA or AG mutation in the GYS1 gene, then the horse has PSSM2.

DIFFERENTIAL DIAGNOSIS
(See Table 10.)
- Muscle cramping induced by ear (Otobius megnini)
- Laminitis
- Colic
- Peritonitis
- Aorto-iliac thrombosis
- Other myopathies

TREATMENT
The treatment chosen depends on the severity of the disease. The general principles are rest; correction of dehydration and electrolyte abnormalities; prevention of complications, including nephrosis and laminitis; and provision of analgesia, and are the same as for all acute myopathies with rhabdomyolysis (see “Myopathies of Horses”).

CONTROL
The feeding of high-fat, low-soluble-carbohydrate diets is useful in the prevention of clinical signs in affected horses with either PSSM1 or PSSM2 and is reported to be useful in controlling the disease.25 Horses should have a regular exercise program, preferably with frequent turn-out to pasture, and be fed a diet rich in long-chain fatty acids with low starch content (<10%) and high in fat (10% of digestible energy).25-27

EQUINE HYPERKALEMIC PERIODIC PARALYSIS

SYNOPSIS
Etiology Defect in sodium channel of skeletal muscle.
Epidemiology Disease of Quarter horses and crossbreds. Inherited as an autosomal-dominant trait with variable penetrance.
Clinical signs Episodes of muscle fasciculation, stridor, muscle weakness, and fiaccid paralysis.
Clinical pathology Hyperkalemia during episodes. Gene probe to detect mutated gene.
Lesions None.
Treatment Palliative. Potassium-free intravenous fluids. Acetazolamide.
Control Selective breeding. Low-potassium diet.

ETIOLOGY
Hyperkalemic periodic paralysis (HYPP) is caused by a heritable defect in the sodium channel of skeletal muscle. The mutation, of which only one form has been identified, results in substitution of a cytosine for guanine, with consequent replacement of phenylalanine by leucine in a transmembrane protein regulating sodium flux across the cell membrane and T-tubule. The disease is transmitted as an autosomal-codominant trait, with the result that homozygotes are more severely affected than heterozygotes, and phenotypic expression (disease severity) differs among heterozygotes.

EPIDEMIOLOGY
The disease is familial and affects Quarter horse and crossbred descendants of a single Quarter horse sire. Impressive. More than 50,000 registered Quarter horses are related to known carriers of the disease. Quarter horses with the disease are presumably selected because they outperform unaffected animals in the Halter classes in which they compete at horse shows, although recent rule changes have changed this practice. The disease occurs in breeds derived from or crossed with Quarter horses, including Appaloosas, American Paint horses, and crossbreds. Of 651 elite performance American Quarter horses, 200 control American Quarter horses, and 180 control American Paint horses (APHs), allele frequency for HYPP in all animals was 0.008. APHs had high prevalence of HYPP of 0.025, and Halter horses had significantly greater allele frequency for HYPP of 0.299, consistent with the alleles associated with the desired phenotype. Approximately 14% of 51 Quarter horses in Mexico have the N/H genotype, with 2% having the H/H genotype. Allele frequencies were 0.157 N and 0.843 normal.
The disease is inherited in an autosomal-codominant manner. Therefore 50% of the offspring of the breeding of a heterozygote and a normal animal will carry the trait, as will 75% of the offspring of the breeding of two heterozygotes. Of the breeding of two heterozygotes, 50% of progeny will be heterozygotes, 25% homozygotes for the mutated gene, and 25% homozygotes for the normal gene. Animals homozygous for the abnormal gene are uncommon, representing only 0.9% of animals tested for the disease. The low prevalence of the homozygote genotype is likely a reflection of severity of disease and the reduced likelihood that homoyzygotic animals will reach sexual maturity.

The risk of a heterozygous animal being affected with periodic paralysis is variable. Most heterozygous horses appear normal and never experience an attack, whereas others have severe episodes starting at a young age. Homozygous horses are much more likely to have severe manifestations of the disease at a young age.

PATHOGENESIS
The abnormality in the sodium channel coded for by the mutated gene predisposes the horse to episodes of complete depolarization of the muscle membrane and flaccid paralysis. The mutation in the sodium channel increases the probability that any one channel is open, with the result that the resting membrane potential in affected horses is higher (less negative and closer to the depolarization threshold) than that of normal horses. This results in frequent depolarizations of individual muscle fibers, causing muscle fasciculations. The weakness associated with severe episodes of the disease results from failure of sodium channels to close after depolarizations. Opening of potassium channels when the muscle is depolarized results in movement of potassium out of the muscle cell and the development of hyperkalemia.

CLINICAL SIGNS
The disease in heterozygous animals is characterized by periods of muscle fasciculation and tremor that progress to weakness, paralysis, and recumbency. Such episodes may last minutes to hours, and most resolve spontaneously. Horses often sweat, have prolaphe of the third eyelid, and have contractions of facial and locomotor muscles during episodes. Episodes may be mistaken for colic. Inspiratory stertor common-ly noted during episodes is probably attributable to laryngeal and pharyngeal dysfunction.

Episodes are more frequent and severe in homozygous animals, and signs of laryngeal and pharyngeal dysfunction, such as stridor and dysphagia, occur in almost all of these animals. Endoscopic examination of homozygotes reveals pharyngeal collapse, laryngopalatal dislocation, and laryngeal paralysis. The disease can manifest in foals as young as 7 days of age. The severity of signs in some homozygotes diminishes with age.

Electromyographic demonstration of myotonic discharges, prolonged insertional activity, and doublets and triplets is a sensitive and specific indicator of the disease.

Horses with HYPP have reduced exercise tolerance compared with normal horses. Homozygotic horses have laryngospasm, airway obstruction, hypoxia, hypercapnia, and ventricular depolarizations during intense exercise, which is not recommended for these horses.

CLINICAL PATHOLOGY
Hyperkalemia (>5.5 mEq/L) during or immediately after episodes is characteristic of the disease, although the existence of a normalakalemic variant has been suggested.

Diagnostic confirmation has in the past been achieved by provocative testing by administering potassium chloride (88 to 166 mg/kg, orally) to suspect horses. However, the development of genotyping has rendered provocative testing obsolete and, for humane reasons and because of the risk of death, its use is not recommended. The test of choice for demonstrating the presence of the mutated gene is a specific gene probe. The probe can be applied to various tissues, but blood or hair, with attached root (a plucked hair), are preferred for diagnostic testing of live animals. This test classifies horses as normal, heterozygous, or homozygous but does not indicate the propensity of heterozygotes to exhibit the disease. Samples can be analyzed in the United States at the Veterinary Genetics Laboratory of the University of California (www.vgl.ucdavis.edu).

DIFFERENTIAL DIAGNOSIS
• Colic
• Laminitis
• Hypocalcemia
• Botulism
• Exertional rhabdomyolysis
• Upper airway obstruction

NECROPSY FINDINGS
There are no characteristic findings on necropsy examination.

TREATMENT
Acute Episodes
Most acute episodes resolve spontaneously or with only minor treatment. The aim in treating more severe or prolonged episodes is to reduce the plasma potassium concentration by intravenous infusion of isotonic potassium-free fluids such as sodium chloride, sodium bicarbonate, or dextrose. Some authors recommend infusion of calcium glucone, but others caution against its use. A practical approach is the slow IV administration of 0.25 to 0.5 mL of 23% calcium gluconate per 1 kg of body weight (125 to 250 mL for a 500-kg horse) diluted in isotonic sodium chloride or, preferably, 5% dextrose. Administration of NaHCO₃ at 1 mL/kg IV has been suggested.

Prevention of Episodes
Maintaining affected horses on a low-potassium diet reduces the frequency with which episodes occur. Alfalfa (lucerne); some oils, including soyabean; molasses; liti salt (a mixture of KCl and NaCl); and many sweet feeds are potassium rich and should be avoided. Grass hay (timothy) and straw and oats, corn, and barley are low in potassium. There are commercial feeds that have a guaranteed low concentration of potassium. Alternatively, diets can be formulated using feed of known potassium concentration, as determined by feed analysis. Care should be taken that diets are nutritious and contain appropriate concentrations and ratios of calcium and phosphorus.

Acetazolamide (2 to 4 mg/kg, every 12 hours) reduces the severity and frequency of episodes and is widely used to control the disease. The drug is poorly absorbed in horses, but the concentration required in plasma of horses to achieve a pharmacodynamic effect is lower than that of humans.

CONTROL
The disease is heritable, and carriers are readily identified; thus, a breeding program to eliminate the disease is feasible.

REFERENCES

MALIGNANT HYPERTHERMIA IN HORSES
Malignant hyperthermia is a disease of Quarter horses and other breeds induced by exposure to halothane, succinylcholine, or similar depolarizing agents and various other stressors. It also occurs in pigs, dogs, and humans. The disease in Quarter horses is caused by a mutation in the BYR1 gene, with subsequent dysfunction of calcium handling within the cell. There is excessive release of calcium from the sarcoplasmic reticulum on exposure to halothane, with development of hyperthermia, hypercapnia, and lactic acidosis, and often death. There is no apparent breed, age, or sex predilection for the sporadic disease. Breed is clearly a predilection for affected Quarter horses. The mutation in Quarter horses can be detected by analysis of the genome.
The clinical signs are rapid onset of hyperthermia, sweating, muscle fasciculation, tachycardia, tachypnea, and muscle rigidity in anesthetised horses. There is acidosis, hypercapnea, and, in acute cases, increases in serum activity of CK. Elevations in CK might not be evident in horses that die peracutely. Treatment is supportive and includes prompt removal of the inciting agent (halothane), cooling, correction of acid-base and electrolyte abnormalities, and prevention of myoglobinuric nephrosis.

PORCINE STRESS SYNDROME
(MALIGNANT HYPERTHERMIA)

SYNOPSIS
Etiology Inherited defect caused by an autosomal-recessive gene at a single locus with incomplete penetrance. Also known as the halothane-sensitivity gene, or porcine stress syndrome (PSS) mutation, which is a single-point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum.

Signs
- Porcine stress syndrome: death during transportation
- Malignant hyperthermia: induced by halothane anesthesia; results in muscular rigidity and death
- Pale, soft, exudative pork: rapid rigor mortis after slaughter followed by excessive dripping of carcass and pale, watery pork; dark, firm, and dry pork is a variation
- Back-muscle necrosis: reluctance to move; acute swelling and pain over back; some may die; subcutac form also possible

DNA-based test for PSS mutation gene.

Lesions Pale skeletal muscles in PSS deaths. Pale muscles in back-muscle necrosis.

Diagnostic confirmation—necropsy findings. Identification of homozygous animals with tests.

Etiology
Considerable attention from breeders has greatly reduced the occurrence of this condition in recent years.
Three closely related stress syndromes occur in pigs. Porcine stress syndrome (PSS) is characterized by acute death induced by stressors such as transport, high ambient temperature, exercise, and fighting, which results in progressive dyspnea, hyperthermia, disseminated vasocostriction, and the rapid onset of rigor mortis. Pale, soft, and exudative pork (PSE) occurs postmortem in some pigs slaughtered by conventional methods. Malignant hyperthermia (MH) is a drug-induced stress syndrome characterized by muscle rigidity and hyperthermia occurring in susceptible pigs following the use of halothane or the muscle relaxant suxamethonium. Back-muscle necrosis of pigs is a special manifestation of PSS.

Malignant hyperthermia also occurs in humans. PSS is caused by an inherited defect as a result of an autosomal-recessive gene at a single locus with incomplete penetrance. It is also known as the halothane-sensitivity gene, or PSS mutation, which is a single-point mutation of nucleotide 1843 in the skeletal muscle gene for the calcium-release channel of the sarcoplasmic reticulum. The PSS defect renders muscle hypersensitive to stimulation by various stressors. In stress-susceptible pigs there is a rapid onset of anaerobic glycolysis and loss of control of skeletal muscle metabolism in response to stress and anoxia.

The gene is commonly known as the halothane-sensitivity gene (HAL gene) because pigs with the homozygous genotype can be identified with the halothane test, which results in malignant hyperthermia. The halothane gene is located within a group of blood-type genes on the same chromosome, allowing identification of affected pigs by blood typing. A single-point mutation in the porcine gene for the skeletal muscle ryanodine receptor channel is associated with malignant hyperthermia in five major breeds of heavily muscled swine. There is then massive muscle contraction and release of heat. Comparison of the sequences of the HAL genes of PSS and normal pigs revealed a single mutation at nucleotide 1843 in the cDNA derived from the HAL gene.

Differential diagnosis list
- Mulberry heart disease
- Acute septicemia attributable to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Intestinal volvulus
- Heat exhaustion
- Suffocation during transportation.

Treatment None.
Control Genetic selection. Reduction of environmental and management stressors.

Epidemiology
Prevalence and Occurrence
This subject needs to be kept in perspective. It has recently been suggested that only 4% of inferior-quality meat is a result of genetics (halothane positive), with the remainder being caused by preslaughter and post-slaughter treatment.
PSS occurs worldwide, but there is considerable breed and area variation in its prevalence. In some European countries the prevalence is a major problem in pig production because of the inadvertent selection for this trait in genetic improvement programs. This underlies the problems of selection based purely on performance and production characteristics.

The prevalence of PSS in the swine population can be determined by the use of screening tests applied on the farm or when pigs enter swine performance test stations.

The halothane test and the CK test are useful for this purpose. A DNA-based test with 99% accuracy is also available. In European breeds, the prevalence varies from 0% to 88%, with up to 100% in the Pietrain breed.
The prevalence of halothane susceptibility is low in the Danish Landrace breed in Denmark. Based on the halothane test, 1.5% of young boars entering a Record of Performance Test Station in Canada were positive reactors. The reactors originated from 7.5% of 107 herds. The halothane succinylcholine test was a more sensitive test because 18% of the same pigs were identified as reactors.

Using a DNA-based test, in a survey of 10,245 breeding swine of various breeds from 129 farms in the United States, Canada, and England, approximately 1 of 5 pigs was a heterozygous carrier of the PSS mutation, and 1% were homozygous. The prevalence of the PSS mutation was 97% for 58 Pietrain, 35% for 1962 Landrace, 15% for 718 Duroc, 19% for 720 Large White, 14% for 496 Hampshire, 19% for 1727 Yorkshire, and 16% for 3446 crossbred swine. The PSS gene frequencies for these breeds were 0.72, 0.19, 0.08, 0.10, 0.07, 0.10, and 0.09, respectively.
The PSS mutation has also been identified in Poland China and Berkshire breeds. These gene frequencies were 30% to 75% lower in Canadian swine than in U.S. swine, with the exception of Yorkshires, for which the gene frequency is threefold in Canadian swine.

Risk Factors
Animal Risk Factors
Susceptibility to the PSS is inherited, and the biochemical events leading to PSE, transport death, or malignant hyperthermia are triggered by several external influences or stressors in the living animal. PSS probably occurs in all breeds of pigs, but the incidence is highest in pigs selected for heavy muscling, and stress-susceptible pigs are leaner and more meaty. These include the Pietrain and Poland China breeds and also some European strains of Landrace, where a score for
muscling and growth rate, feed conversion, and back fat has been included in the selection index. A recent study has shown that there are considerable breed differences, in that halothane-stress-susceptible pigs and Hampshires suffer more severely from heat stress than Yorkshires, Danish Landrace, and Duroc boars.

There is a correlation between halothane susceptibility and carcass traits. Halothane status is the most important factor influencing pork quality, although preslaughter handling and stunning method also influence the carcass quality.

Halothane-positive animals usually score higher for visual conformation of the loin and ham than halothane-negative pigs. The progeny of rector boars are also more susceptible than the progeny of nonreactors. Until recently it was thought that the major limitation of the halothane test was that it identified only those pigs that are stress-susceptible to the syndrome. It is now known that the halothane-sensitivity gene is expressed in heterozygous pigs, where it is likely to cause poor carcass quality.

Landrace pigs can be divided into those that are sensitive to halothane and develop PSE pork postmortem, those that are resistant to halothane but develop PSE pork, and those resistant to halothane and PSE pork (the normal pig). Muscle from pigs susceptible to malignant hyperthermia and PSE pork has significantly higher glucose-6-phosphate levels and lower phosphocreatine under thiopentone anesthesia than muscle from pigs susceptible to PSE and normal pigs. Altered muscle fiber type is not the primary basis of the disease complex.

Environmental and Management Risk Factors
The most important precipitating factors are transportation at high environmental temperatures and humidity, exhaustive exercise, and, under experimental conditions, the more specific reaction toward the anesthetic halothane. Response of pigs to transport is dependent on genotype, particularly at high temperatures such as 36°C (97°F). Experimentally, psychological mechanisms can precipitate the PSS. The effects of mixing, transportation, and duration of lairage can have profound effects on the carcass characteristics of susceptible pigs. Death during transportation and PSE are associated with fear, defensive or aggressive reactions in unfamiliar social environments, and conflict with other unfamiliar pigs or people. Other activities that may trigger malignant hyperthermia include restraint, mating, farrowing, fighting, and vigorous exercising.

Economic Importance
The economic losses associated with PSS are attributable to mortality from transport death and inferior meat quality as a result of PSE pork. As a result of the excessive rates of production of lactic acid and heat, sarcoplasmic proteins denature, thereby causing a deterioration of the water-binding capacity of muscle. The increased osmotic activity resulting from end products of hypermetabolism causes an influx of water from the extracellular space, resulting in hemococoncentration and increased intramyofiber water content. The muscle becomes pale, soft, and exudative, sour-smelling, and loose textured. The shrinkage resulting from water loss during storage, transport, and processing of the carcass is the major cause of wholesale losses at pork-packing plants. PSE carcasses yield less bacon, and the drip loss from fresh PSE meat is more than doubled compared with normal carcasses. Another cause of lost revenue with MH-susceptible swine is their decreased average daily weight gains, conception rates, litter sizes, and boar breeding performance.

PATHOGENESIS
The molecular basis for susceptibility to the PSS is a hypersensitive triggering mechanism of the calcium-release channel of skeletal muscle sarcoplasmic reticulum. The calcium channel, also known as the ryanodine receptor, plays a critical role in the initiation of muscle contraction. The PSS defect renders muscle hypersensitive to stimulation by various stressors. Stress-susceptible pigs cannot tolerate stress and lose control of skeletal muscle metabolism. The stress may be from external influences such as transportation, fear and excitement, or halothane anesthesia. There is excessive catecholamine release and the sudden onset of anaerobic glycolysis of skeletal muscle, excessive production of lactate, and excessive heat production, which, in conjunction with peripheral vasoconstriction, leads to hyperthermia. Following exertional or thermal stress, susceptible pigs undergo more extensive physiologic change than do resistant pigs. Halothane-sensitive pigs are more susceptible to becoming nonambulatory when subjected to multiple stressors and may be more prone to producing inferior pork products. The blood glucose concentrations are dependent on the MH genotype, with the homozygous-positive animals having the highest levels and the homozygous-negative animals having the lowest. The changes in carbohydrate metabolism at rest in MH-positive animals are caused by latent increases of intracellular Ca²⁺ concentrations. Under physical load conditions there is higher lipolysis, which may be the result of an indirect activation of the lipolytic system via catecholamine-induced cAMP turnover.

Depending on the nature, severity, and duration of the stress, the syndrome may manifest in different ways:
- The porcine stress syndrome causes rapid death following severe stress.
- The PSE pork and dark, firm, dry (DFD) pork are seen after slaughter, which might have been preceded by mild stressors during lairage.
- The malignant hyperthermia is drug-induced.

PSE pork is attributed to increased glycolysis after slaughter. In muscles that develop DFD pork, the muscle glycogen is already depleted before slaughter. When PSE develops in a muscle, pH drops to values lower than 5.8 at 45 minutes after death. In normal muscles, the pH decreases from approximately 7 in living muscles to 5.3 to 5.8 at 24 hours after death. The lower pH in PSE muscles, combined with a high carcass temperature within the first hour after death, causes the proteins in the muscles to denature. This contributes to the pale color of PSE meat and to its reduced water-holding capacity. Development of muscles with PSE characteristics seems to be initiated by a combination of lower muscle pH already at exsanguination and a faster pH decrease.

Malignant hyperthermia is the drug-induced and often fatal stress syndrome occurring in susceptible pigs within 3 minutes following the inhalation of a mixture of halothane and oxygen. Susceptible pigs develop limb rigidity and a hyperthermia, which are not easily reversed and may result in death. There is an increased rate of intracellular ATP hydrolysis leading to a progressive failure of ATP-dependent Ca²⁺ accumulation by the sarcoplasmic reticulum and/or the mitochondria, with a rise in myoplasmic concentration of Ca²⁺ and consequent contraction of muscle. The same molecular defect occurs in lymphocytes from affected susceptible pigs. There is no histophysiologic evidence of cardiac abnormalities in MH-susceptible pigs. The mitochondria from predominantly red muscle fibers have a greater calcium-binding capacity than those from predominantly white muscle-fiber areas. There is extreme rigidity of skeletal muscles, hyperthermia, tachycardia, cardiac arrhythmia, an increase in oxygen consumption, lactate formation and high-energy phosphate hydrolysis in muscle, respiratory and metabolic acidosis, and a rise in the CK activity and concentrations of potassium, lactate, glucose, free fatty acids, and catecholamines in blood. There is a large release of glucose and potassium from the liver, which contributes to the hyperglycemia and hyperkalemia. There is a marked β-adrenergic stimulation, which is responsible for the heat production in MH-susceptible pigs. However, the β-adrenergic response in stress-sensitive and stress-resistant pigs is inconsistent. The lactic acidemia is severe because of the overproduction of lactate peripherally and failure of normal lactate uptake.

Malignant hyperthermia can also be induced using methoxyflurane, isoﬂurane and enfuran, and succinylcholine. Exposing stress-susceptible pigs to halothane or exercise induces glycolysis, but the
mechanisms are different. There are no histochemical differences between muscles of susceptible and normal swine. There is some indication that halothane causes a transient but significant vasoconstrictive action, which could be a contributing factor in initiating the severe reactions in malignant hyperthermia. Electron microscopy of platelets from stress-susceptible pigs reveals a defect characterized by dilatation of the open canalicular system.

CLINICAL FINDINGS
Porcine Stress Syndrome (Transport Death)
Death during or following transport to market may be significant and is more prevalent when overcrowding occurs and during the hot summer period. If seen alive, affected pigs initially show a rapid tremor of the tail, general stiffness associated with increased muscular rigidity, and dyspnea to the extent of mouth-breathing. The body temperature is elevated, often beyond the limits of the clinical thermometer, and there are irregularly shaped areas of skin blanching and erythema. At this stage the affected pig is frequently attacked by other pigs within the group. The pig collapses and dies shortly afterward, and the total time course of the syndrome is generally of the order of 4 to 6 minutes.

Malignant Hyperthermia
Malignant hyperthermia is also a manifestation of the PSS. It may be induced in stress-susceptible pigs by stress and injectable succinyl choline, acepromazine, ketamine, or inhalation anesthesia with potent volatile anesthetics such as halothane or isoflurane. It is characterized by the development during anesthesia of increased muscle metabolism with muscular rigidity, lactic acidosis, a marked increase in basal metabolic rate, increased oxygen consumption and carbon dioxide production, severe hyperthermia and tachycardia, tachyarrhythmia, and death.

Death is a result of the peripheral circulatory changes that are produced by severe acidosis, vasoconstriction, hyperkalemia, reduced cardiac output, and hypotension. Once fully developed, the syndrome is irreversible. The syndrome poses a hazard in swine anesthesia, which can be averted by prior medication with dantrolene and has received considerable study as a model for an analogous syndrome in humans. It has also been used as a method for determining stress susceptibility for genetic selection programs.

Pale, Soft, and Exudative Pork
In stress-susceptible pigs, after slaughter, the inferior quality of the meat, with its pale, soft, exudative (PSE) characteristics, is obvious. This is caused by excessive postmortem glycolysis with lactic acid production and a rapid fall in muscle pH, with depigmentation and reduced water binding as a consequence. In affected muscle, rigor mortis occurs rapidly after slaughter but then decreases, so that affected carcasses have been "set" and postmortem drip is excessive. Affected pork has a pH of less than 6 and generally a temperature of 41° C (106° F) or greater 45 minutes after slaughter, compared with the normal pork with a pH above 6 and a temperature less than 40° C (104° F). This causes denaturation of muscle proteins, leading to affected meat that has inferior taste, cooking, and processing qualities and does not accept curing as readily. The occurrence of this syndrome is considerably influenced by the stress of transport and handling before and during slaughter, and this aspect of the syndrome is of major economic importance. Rapid chilling helps prevent PSE, but chill type has no effect.

Dark, Firm, and Dry Pork
Dark, firm, and dry (DFD) pork has darker color and higher ultimate pH than normal meat. In muscles that develop DFD, the muscle glycogen is already depleted before slaughter, which may be related to prolonged transport with fasting.

Back-Muscle Necrosis
Acute necrosis of the longissimus dorsi occurs in German Landrace pigs and other breeds. The acute syndrome lasts approximately 2 weeks and is characterized by swelling and pain over the back muscles, with arching or lateral flexion of the spine and reluctance to move. The swelling and pain then subside, but there is atrophy of the affected muscle and development of a prominent spinal ridge. Some regeneration may occur after several months. Acute cases may die. The syndrome occurs in young adults weighing from 75 to 100 kg. The mild form may be undetectable except for pigs lying down near the feed trough. In the severe form, affected pigs may assume the dog-sitting position with a hunched-up back.

CLINICAL PATHOLOGY
Several testing methods are available for predicting susceptibility.

Halothane Test
The halothane test is highly reliable for the identification of pigs that are homozygous for the single recessive gene responsible for susceptibility to PSS. However, the test is not 100% accurate because of the incomplete penetrance of the halothane sensitivity trait (not all homozygous MH-susceptible pigs react by developing limb rigidity). Penetration of the halothane sensitivity trait is estimated to vary from 50% to 100% depending on the breed, herd, and investigators. The test detects the worst clinical outcomes, and it will not identify all the pigs that will develop PSE. There is now evidence that it will detect the heterozygote. Stress-susceptible pigs are sensitive to halothane at 8 weeks of age, and if the anesthetic challenge is removed immediately after obvious signs of limb rigidity develop and before the development of fulminating hyperthermia, the mortality from the procedure is negligible. Pigs that remain unreactive for a challenge period of 5 minutes are considered normal.

A halothane-sensitive muscle defect can be present in certain individuals that do not develop rigid malignant hyperthermic episodes on brief exposure to halothane. A longer halothane exposure combined with succinylcholine is required if these false negatives are to be identified. The halothane test has good predictive value for the occurrence of PSE. However, there may be breed variations, as mentioned previously.

A decrease in the amplitude of the phosphocreatine (PCr) signal in the in vivo 31 P nuclear magnetic resonance spectrum of skeletal pigs is an early and 100% predictive measurement for the detection of malignant hyperthermia in anesthetized piglets. Nuclear magnetic resonance techniques such as magnetic resonance imaging and magnetic resonance spectroscopy are sensitive diagnostic aids for detecting the onset of PSS in young animals and for following the metabolic changes in muscle tissue during the syndrome.

Halothane concentration markedly affects the outcome of halothane testing, and either higher halothane concentrations or longer exposure might be required to identify positive reactors in a heterogeneous population. The ionophore A23187, a lipophilic carboxylic antibiotic that binds and transports divalent cations across both natural and artificial membrane bilayers, allows clear differentiation between the muscles of normal and pathologic animals and may be a useful adjunct to the halothane test.

Blood Creatine Kinase Levels
The blood creatine kinase (CK) levels are higher in stress-susceptible pigs. Pigs are subjected to a standard exertion test, and blood samples are taken 8 to 24 hours later and analyzed for CK. The original research indicated a good correlation between CK levels and the halothane test. There is also an increase in CK levels in pigs as they are transported from the farm to the abattoir. However, not all pigs that develop PSE have increased serum levels of CK. Increased CK activity is highest in stress-susceptible pigs of the Phi-B and their total plasma CK levels are higher than those of nonreactors. The initial test was modified so that blood could be collected as drops on a filter paper and sent to a laboratory for identification by a bioluminescent technique. A recent evaluation of a commercial CK screening test using the method of bioluminescence compared with the halothane challenge test on young boars entering a Record of Performance Test Station revealed that it was an inadequate indicator of susceptibility.
to PSS or MH. In a different study the CK levels of piglets 8 to 10 weeks of age predicted halothane-induced stress syndrome with an accuracy of 87% to 91%.

Plasma pyruvate kinase activity has been compared with CK activity as an indicator of PSS. Both enzymes are increased significantly in homozygous halothane-reacting pigs compared with nonreacting pigs. Pyruvate kinase activity was less variable within groups than CK activity, which may allow more effective discrimination between the two different genotypes. However, age-related effects and the failure to identify heterozygotes may restrict the use of plasma pyruvate activity as a diagnostic test.

**Blood Typing**

Blood typing is also used as a method for the identification of susceptible pigs. On one of the chromosomes of the pig, a region with four known loci has been identified. These loci contain the genes responsible for variants of the enzymes 6-phosphogluconate dehydrogenase and phosphofructokinase (PHK). The H-blood group system is determined by one of the loci, and halothane sensitivity is also determined by genes at a locus in this region. This region is of special interest because a close connection has been found between this and important carcass traits such as the PSE condition. Thus blood grouping may be used to detect halothane-sensitive pigs and heterozygote carriers.

A DNA-based blood test can now be used to detect the HAL gene status. It can be adapted for rapid batch analysis of many samples simultaneously, is less invasive, and can be applied to as little as 50 µL of blood. The test is more than 98% accurate, is cost-effective, and can be used to determine the prevalence of the PSS mutation in various breeds of swine in various countries. A recent study showed that 23% of pigs classified as Hal-1843-free based on a DNA test responded abnormally to halothane anesthesis.

**Pale, Soft, and Exudative Pork**

Pale, soft, and exudative pork (PSE) is evaluated by a meat quality index that combines meat color, pH at 24 hours postmortem, and water-binding capacity. Susceptible lines can be identified by carcass inspection and the results applied to sibling or progeny selection. A recent approach is the measurement of mitochondrial calcium efflux. Mitochondria isolated from MM longissimus dorsi muscle exhibit a rate of Ca\(^{2+}\) efflux twice that of normal pigs. Most of the tests readily predict the worst examples of the syndrome but are not sufficiently precise to be able to identify tendencies toward it, which restricts their value in breeding programs.

**Erythrocyte Osmotic Fragility**

Erythrocyte osmotic fragility may be correlated with malignant hyperthermia and is being examined as a possible aid in the determination of susceptibility.

**Other Tests**

Any reliable test that can identify stress-susceptible pigs without using halothane testing is attractive. Increased peroxidation of the erythrocytes may be an improved diagnostic test for PSS. Differences in the levels of cortisol, creatinine, aspartateaminotransferase, and lactate dehydrogenase are highly significant between halothane-sensitive and halothane-negative lines of pigs.

An allele-specific PCR (AS-PCR) technique has been developed. A PCR followed by reduction endonuclease assay has been developed and used on plucked hair as a source of genomic DNA. In a test with this method, 9 of 12 Pietrains tested were homozygous or heterozygous. A one-step procedure has been developed called mutagenically separated PCR (MS-PCR).

**NECROPSY FINDINGS**

In PSS, rigor mortis is present immediately following death, and carcass putrefaction occurs more rapidly than normal. The viscera are congested, and there is usually an increased quantity of pericardial fluid and pulmonary congestion and edema. The muscles—especially the glutus medius, biceps femoris, and longissimus dorsi—are pale, wet, and soft. In back-muscle necrosis, these changes appear grossly to be confined to the epaxial musculature. Histologically, the lesions in skeletal muscle may be minimal and are usually not identified by autolysis. In some instances only interstitial edema is visible, whereas in animals that have survived repeated episodes there is obvious phagocytosis of degenerate myofibers, with ongoing regeneration and fibrosis. The most typical microscopic finding is hypercontraction of myofibers, characterized by division of the cell into irregularly sized segments by transverse and sometimes branching bands. Degenerate sarcoplasm of a floccular or sometimes hyaline character may be present. Degenerative changes may also be detected in myocardial cells.

**DIFFERENTIAL DIAGNOSIS**

The acute nature of porcine stress syndrome (PSS) and its relation to stress serve to differentiate it from most other syndromes causing sudden death in market- and adult-sized pigs. The sudden death syndrome must be differentiated from:

- Mulberry heart disease
- Acute septicemias attributable to salmonellosis, erysipelas, pasteurellosis, and anthrax
- Other causes of sudden death, including intestinal volvulus, heat exhaustion, and suffocation during transportation
- Hypocalcemic tetany resulting from severe vitamin D deficiency, which can produce a similar clinical syndrome
- Porcine viral encephalomyelitis, which can also result in a similar clinical syndrome in post-weaned pigs; pathologic and biochemical examinations differentiate these from the PSS

**TREATMENT**

Early recognition enables successful treatment. Any drug administration should cease. Aggressive cooling using ice packs and alcohol baths should be instituted. The acute syndromes are usually not treated. Several drugs are available for the protection of pigs against drug-induced malignant hyperthermia. A combination of acepromazine and droperidol will delay the onset or prevent the occurrence of halothane-induced malignant hyperthermia. Dantrolene is also effective for treatment and prevention. The therapeutic dose is 1 to 3 mg/kg IV and 5 mg/kg orally as a preventative. Carazolol is effective for the prevention of transport death when given 3 to 8 hours before transportation and improves meat quality compared with untreated susceptible animals. Acute back necrosis has been treated successfully with isopyrin and phenylbutazone. Experimentally, the supplementation of the diets of stress-susceptible pigs with vitamin E and C will provide some protective effect on cell-membrane integrity.

**CONTROL**

The control of this syndrome depends on genetic selection and possible eradication of the PSS mutation and reduction of the severity of stress imposed on pigs.

**Genetic Selection**

The best strategy for control of this complex is not clear. Several factors must be considered. Swine homozygous for the PSS mutation are at very high risk for developing PSS and severe PSE to make them useful for market pigs. They are used primarily as a source of the PSS mutation for breeding programs and research purposes. Using swine that are heterozygous for the PSS mutation as market pigs may be advantageous. They benefit from the positive effects of the
mutation, have minimal risk of developing PSS, and may have acceptable prevalence and severity of PSE, if the environmental and management risk factors that precipitate PSE are minimized during marketing and slaughter. The mutation is not a prerequisite for leanness and muscularity, and it is possible for breeders to eradicate the gene from their breeding stock. The negative effects of the halothane gene on fresh pork quality are well known. However, such a policy may result in the loss of an easily accessible and cost-effective selection criterion for favorable carcass characteristics. The PSS mutation has been used successfully in most swine breeds for increasing leanness and muscling. With the development of the DNA-based test for the PSS mutation, the mutation can be selected for with high precision and accuracy, and its expression can be finely controlled in a breeding program.

The various testing methods described under “Clinical Pathology” are used to identify pigs with the halothane gene. The tests can be applied to breeding stock entering swine performance test stations or on a herd basis. A reliable diagnostic test such as a DNA-based blood test to identify the gene will provide the basis for elimination of the gene or its controlled inclusion in swine breeding programs.

Management of Stressors
Control through reduction of stress is not easily applied because frequently the syndrome is induced by routine minor procedures within the piggery. The incidence of transport deaths or the necessity for immediate slaughter salvage of severely stressed pigs on arrival at the abattoir and the occurrence of PSE meat characteristics are a significant economic problem in some countries. The necessity to climb an upper deck in the transport poses a significant stress, and the use of single-deck transports or mechanical lifts for multiple-deck transports, and the shipment of pigs in containers, has resulted in a decreased incidence. The provision of spacious, well-ventilated transport vehicles and spray-cooling of pigs on arrival at the holding pens is also beneficial. Pigs should not be slaughtered directly after arrival at the abattoir and should be rested for at least 1 to 2 hours if they have been stressed only by transportation. In cases of severe physical exertion, even more time should be allowed for recovery. Where possible transport distance should be kept to a minimum, and transport should be avoided on excessively hot days.

PIETRAIN CREEPER PIGS
A progressive muscular weakness is found in stress-susceptible Pietrain pigs. A similar condition might have been seen in Landrace. It was originally described in one to three herds in the United Kingdom. It is probably an autosomal-recessive gene and is a progressive familial myopathy. In each litter one-quarter to one-third of piglets may be affected. The syndrome commences with muscle tremor at 2 to 4 weeks of age, in the hindlimbs progressing to the forelimbs, followed by reluctance to stand, limbs being flexed, and standing on tip-toe, with walking on flexed carpal joints leading to complete recumbency by 12 weeks of age. At this stage the pigs move with a creeping gait with the limbs flexed. The pigs remain alert and feed and grow normally. There are no neuropathologic lesions, but there are myopathic changes, especially in the forelimbs. In these muscles there are very variable muscle cells with internal nuclei.

ASYMMETRIC HINDQUARTER SYNDROME OF PIGS
Asymmetric hindquarter syndrome of pigs was first reported in Germany and Belgium in 1968. In these cases perineurial fibrosis was a feature, and it was thought that the condition resulted from either a neurogenic atrophy or a periaricular fibrosis extending to the peripheral nerves.

In this syndrome variable asymmetry of the hindquarters is evident during early growth of the animal and obvious by 80 kg live weight. An asymmetric distribution of subcutaneous fat is also noted, and possibly skin dimpling. The muscle most frequently affected is the semimembranosus, followed by the semitendinosus, biceps femoris, adductor femoris, and gracilis. The muscles show changes that can be described as myofibril degeneration, interstitial fibrosis, and dystrophic changes.

Several breeds, including Landrace, Large White, and Hampshire, have been found affected, but the problem is generally restricted to certain herds and to certain families within these herds, suggesting that a genetic liability exists for this condition. The mechanism of inheritance studied from test matings is not simple. Whatever the cause, there is a marked reduction in the number of muscle fibers. Both sexes may be involved, and the condition may involve either hindlimb.

Despite a marked reduction in muscle mass, there is no detectable abnormality in gait. The cause is unknown, although it appears to result from suboptimal muscle growth rather than degenerative loss. In the only cases recorded from outside Europe, a group of seven Australian pigs were examined in detail; in one of these pigs the affected semitendinosus weighed only 41% of the normal, unaffected one. Peroneal fibrosis and myopathy have been observed in some cases.

FURTHER READING

PORCINE CONGENITAL SPLAPELEG (SPLAYLEG SYNDROME IN NEWBORN PIGS)
Porcine congenital splayleg (PCS) is also called spraddle leg, but more usually myofibrillar hypoplasia. This may be an erroneous term because this hypoplasia occurs in many normal pigs and may be a normal feature of postnatal muscle growth. This clinical condition of splayleg occurs in newborn piglets in most countries and is characterized by a temporary inability to stand with the hindlimbs.

ETIOLOGY
The etiology is unknown, but based on epidemiologic evidence, it is multifactorial. The current hypothesis is that the disease is caused by an interaction of genetic and non-genetic factors, a polygenic mode, or expression of many genes without dominance. Splayleg is not characterized by general muscular atrophy in the affected hindlimbs.1

The studies of Czech workers have suggested that the patho-morphology of the condition resembles that of glucocorticoid-induced myopathy in humans and animals. Dexamethasone given to minisows from the first to the last days of pregnancy produced a disorder characterized by splayleg syndrome with retardation of both muscle growth and myofibrillogenesis in their newborn piglets. It has also been experimentally produced following the administration of pyrime thamine.

There may be pathways indicated in gene expression for the further investigation of congenital splayleg.1 It may be that the combined differential expression of MAFbx (a major atrophy marker) and P311 (a novel protein down regulated in all PCS muscles) is of potential in the diagnosis of subclinical PCS.2

EPIEMIOLOGY
The prevalence of the disease in the United Kingdom is 0% to 4%, and the morbidity in affected herds varies from 2% to 27%. The case-fatality rate is approximately 50% and is attributable to crushing, chilling, and starvation because affected piglets are not able to move around normally. The disease is more common in the Pietrain, Welsh, Landrace, and Large White breeds of swine; Landrace pigs may be especially susceptible. This suggests a genetic basis, but test-matings, with the exception of a few, have not been successful in reproducing the disease. On most farms the disease affects both male and female piglets. In a recent
retrospective analysis of the incidence of the disease in a swine herd over a period of 5 years, the overall frequency was 1.74 times greater in males than females, and the birth weight of splayleg piglets tended to be subnormal. The environmental factors that have been associated with some outbreaks include slippery floors, a dietary choline deficiency, and the ingestion of *Fusarium toxin* by pregnant sows. Choline deficiency is unlikely to be a factor, and no other factors have been substantiated as etiologic factors or epidemiologic determinants.

### PATHOGENESIS

The pathogenesis of the disease is unclear. In affected pigs there is myofibrillar hypoplasia, but this is also a feature of many muscles in normal pigs. There are simply too few maturing type I fibers in the muscles, particularly of the foreleg, lumbar epaxial group, and the hindlimb, to carry weight. The semitendinosus appears to be the most significantly affected muscle. However, because myofibrillar hypoplasia may also be present in normal unaffected littermates, it has been difficult to explain the pathogenesis of the muscular weakness. The use of morphometrics has enabled the detailed determination of the myofibrillar hypoplasia. In addition to myofibrillar hypoplasia, in splayleg pigs there is a higher content of sarcoplasmic RNA, reflected ultrastructurally by the presence of numerous ribosomes. The extramyofibrillar space was also filled with glycogen in splayleg pigs. In myofibrillar hypoplasia induced with glucocorticoids given to the pregnant sow, none of the pigs had splaylegs, but the extramyofibrillar space contained little glycogen. There were also many glycogen-filled phagosomes and residual bodies, indicating a difference in the metabolism of glycogen in the first 2 or 3 days after birth. In a study of natural cases there was hypoplasia, but there was an increased accumulation of glycogen, especially within the large extramyofibrillar spaces, in comparison with the normal pigs. These authors also found an anomalous distribution of glucose-6-phosphatase in splayleg-affected muscles, in that the activity was concentrated at the periphery of the extremely dilated cisternae of the sarcoplasmic reticulum. In the normal muscles that enzyme activity was normal. This distribution could account for the slower utilization of glycogen in affected muscles and therefore would account for the build-up. Quantitative image analysis of skeletal muscle revealed that the arrangement of the myofibrils within the fascicles of affected and unaffected pigs was different.

Some studies have found both quantitative (hypoplastic type) and qualitative (dystrophic type) insufficiencies in affected pigs that represent a temporary perinatal developmental disturbance. This could explain the muscular weakness and the recovery that occurs.

### CLINICAL FINDINGS

There is a temporarily impaired functionality of the hindleg muscles immediately after birth. Essentially, the adductors are not as powerful as the abductors.

Larger litters may be more affected, possibly because these tend to be born earlier. The clinical signs are usually obvious in 2 to 3 hours after birth when the litter should be standing and walking around the creep area. Affected piglets are unable to stand, their hindlimbs are splayed sideways or forward, and the animals rest in sternal recumbency. Sometimes the forelimbs are also splayed. Most severely affected piglets are unable to move; less severely affected animals are able to move slightly. Many pigs have soiled hindlimbs and perineum as a result of being unable to stand. As a result, the piglets are likely to be crushed or have difficulty gaining access to their source of nourishment. Affected piglets are normal in other respects, have a normal appetite, and will suck the sow if placed near a teat. In the experimental induction there was hypoplasia but no clinical signs, which is further evidence for suggestions that the condition has a threshold for clinical signs and has strong maternal influences.

### TREATMENT

Treatment can be successful. If the pigs are able to suck or if they are fed artificially for 2 to 4 days, recovery will occur within 1 week in about 50% of cases. The ambulatory capacity of affected pigs can be improved, and mortality reduced, by tapping or loosely tying together the hindlimbs for a period of up to 1 week. The method of loose tying of the hindlimbs consists of a figure-of-eight bandage (2.5-cm-wide adhesive tape) being fixed around the metatarsal bones, leaving a space between the legs of up to 7 cm depending on the size of the piglet. The legs should be tied together within a few hours after the syndrome is obvious; a delay of several hours will decrease the prognosis. The provision of a nonslip floor surface such as a carpet or sack may also be helpful. Many farmers will tell you that repeated massaging of the limbs will also improve the survival rate.

### CONTROL

Whether or not to cull the boar depends on the pedigree value of the animal, the incidence of the disease, and the probability that the boar is responsible. There is no evidence that the disease is monogenic. However, the incidence is highest in the Landrace breed, which suggests a hereditary predisposition. In deciding whether to use a suspected carrier animal, there is a need to distinguish between different situations. The consequences of disease are felt differently at the different levels of organization of the pig industry. A boar of high merit for performance traits may be more economical to retain as breeding stock even though some progeny are affected with the disease than a less superior boar whose progeny are unaffected. If stress of the pregnant sow is a factor, control of the disease may be dependent on the selection of stress-resistant boars and sows.

Concurrent disease should be controlled; producers report a higher percentage of splayleg piglets after a period of porcine respiratory and reproductive syndrome (PRRS) infection. There are also suggestions that induced early farrowing and zearalenone poisoning may also be complicating factors to prevent.

**Inherited Diseases of Bones**

Congenital skeletal abnormalities are relatively common in large animals and can be genetic, teratogenic, or nutritional in origin.\(^1\) Exposure of developing fetuses to a wide variety of toxic compounds, maternal mineral deficiencies or imbalances, or exposure to one of a number of infectious agents at certain stages of gestation can create skeletal lesions indistinguishable from those caused by a genetic abnormality. In some cases, teratogenic or nutritional causes of skeletal abnormalities can appear very similar to genetic causes, and distinguishing among them can be challenging.\(^2\) For example, chondrodysplasia associated with intrauterine zinc or manganese deficiency have similar clinical features and histologic lesions to mild forms of hereditary chondrodysplasia.\(^3\) Therefore, historical data are essential in any attempt to distinguish genetic and acquired causes of skeletal lesions; as many animals as possible should be examined, and samples should be collected for future analysis, such as genetic testing.

### ETIOLOGY

Over 350 defects in cartilage and bone development are identified in humans.\(^4\) Although substantially fewer are identified in large animals, this large number in humans underscores the many potential diseases in animals. The situation in many production animal industries is compounded by the “founder effect” and widespread use of elite sires by means of artificial insemination that leads to the frequent emergence of recessive genetic defects, which cause important economic and animal welfare concerns.\(^5\) Table 15-10, modified from Dittmer and Thompson,

provides a listing of currently recognized inherited skeletal diseases of livestock, the associated mutations, and mechanisms underlying the disease.  

**PATHOGENESIS**  
Bone development and remodeling is a complex process involving timely expression and control of numerous genes and epigenetics factors, and there is increasing understanding of the role of these factors in creation of bone and cartilage. The large number of genes involved in osteogenesis and cartilage formation and development, and the crucial and nonredundant role of many of these genes, means that a wide range of skeletal defects occur in humans and domestic animals. A variety of transcription and growth factors are identified as being involved in the pathogenesis of skeletal defects. This allows etiologic, rather than morphologic, classification of diseases and abnormalities. Osteochondrodysplasia (or skeletal dysplasia) includes generalized abnormalities in chondro-osseous tissues, whereas dysostosis refers to a localized malformation of an individual bone or group of bones. Osteochondrodysplasias are now mostly classified according to the underlying defect, rather than the morphologic presentation. Most of the skeleton develops through processes involving endochondral ossification, and abnormalities in cartilage formation or structure can have widespread effects on the skeleton. Defects in cartilage formation that result in skeletal abnormalities are called chondrodysplasia. Achiordonoplasia, referring to an absence of cartilage, should be reserved for diseases characterized by a lack of cartilage, rather than abnormalities in its composition or structure.
CLINICAL FINDINGS
Animals with acquired defects often have substantial variation in clinical signs and lesions and can improve over time, whereas animals with disease caused by genetic defects usually have a consistent clinical presentation and pathology. Clinical signs of the various diseases are described under those headings.

Diagnosis
If a disease is determined to be of genetic origin, a number of approaches can be used to detect mutations, include sequencing candidate genes, single-nucleotide polymorphism array with genome-wide association studies, and exome or whole-genome sequencing. Use of genome-wide, high-density single-nucleotide polymorphism (SNP) panels, or next-generation genomic analysis, combined with an understanding of livestock populations, allows for rapid positional identification of genes and mutations that cause inherited defects. However, a thorough understanding of the history of the animal’s disease, its clinical presentation, and its lesions is essential for establishing a reliable diagnosis.

Differential diagnoses for inherited skeletal diseases of animals are shown in Table 15-11 (modified from Dittmer and Thompson).

TREATMENT AND CONTROL
There is no effective treatment for genetic diseases, and affected animals are usually euthanized. Control is based on an understanding of the mode of inheritance, identification of carrier animals (for diseases with recessive inheritance), and selective breeding or testing and removal of heterozygotes from the breeding pool.

INHERITED OSTEOGENESIS IMPERFECTA
The term osteogenesis imperfecta covers a heterogeneous group of connective tissue diseases caused by quantitative or qualitative defects in type I collagen.

The disease is recorded as being inherited in Holstein–Friesian cattle and New Zealand Romney sheep.

Cattle
It is transmitted as an autosomal-dominant trait. Calves are clinically abnormal at birth, with the main presenting signs being bright-pink teeth and slackness of the flexor tendons on all four feet so that the animals are unable to stand. The calves become progressively worse, to the point where they cannot walk. The full list of abnormalities in this syndrome includes smaller-than-normal body size at birth, a dome-shaped cranial vault, and fragility of bones, manifested by multiple fractures occurring during birth. The defect is one of connective tissue cells in which there is a faulty production of collagen and intercellular cement. Radiologic examination demonstrates growth-arrest lines and multiple fractures in the long bones and thin dentine and enamel layers on the teeth, which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

A syndrome of simple bone fragility occurs in Charolais cattle and is called osteogenesis imperfecta.

Sheep
The disease in New Zealand Romney sheep is similar to that in Holstein–Friesian cattle with additional lesions of thickness of the diaphyses and reduction in size of the medullary cavity, moderate brachynathia inferior, subcutaneous edema, skin fragility, and a dark blue color of the sclera. It is inherited as an autosomal dominant trait, and was thought to have developed as a new mutation during birth. The defect is one of connective tissue cells in which there is a faulty production of collagen and intercellular cement. Radiologic examination demonstrates growth-arrest lines and multiple fractures in the long bones and thin dentine and enamel layers on the teeth, which are pink because of the exposed condition of the enlarged pulp. The excessive mobility of the joints results from the small bulk of the ligaments and tendons.

REFERENCE

INHERITED DWARFSM
Most inherited food animal dwarfs are chondrodysplastic, and the disease occurs in cattle and sheep.

Sheep
Brazilian hair sheep of the Cabugi breed, which are typically shorter and more compact than other breeds, have a form of skeletal dysplasia characterized by lambs born with craniofacial abnormalities and dwarfism that die at 2 to 6 months of age. Dwarf lambs are much smaller than normal, with short legs, a domed head with superior brachynathia, sphenoidal deformities, and exophthalmic eyes situated more laterally in the head than normal. There is disproportionate shortening of the appendicular bones. The disease is inherited as an incomplete dominant trait, with the shortened face, a feature of the Cabugi breed, representing the heterozygous state and the more severe, often lethal, dwarfism occurring in homozygotes.

A syndrome of dwarfism, brachynathia, cardiomegaly, and renal hypoplasia (Ellis van Creveld syndrome) occurs in Pol Merino/Merino sheep in Australia. The disease is a lethal genetic disorder associated with homozygosity in genetic material located toward the distal end of chromosome OAR2, from 220,932,050 to 221,939,408, which includes approximately 25 genes. Segregation analysis suggests the disorder is transmitted as an autosomal trait with a recessive mode of inheritance. Affected lambs are dwarfs with multiple defects in the skeleton, heart, liver, and kidneys.

Cattle
Snorter Dwarfs
Snorter dwarfs are no longer important because of successful efforts in eliminating carriers of the gene. These calves are short-legged, have normal size, and protruding lower jaws. The mandibular teeth may protrude 2 to 4 cm beyond the dental pad, preventing effective grazing and necessitating hand-feeding if the animal is to survive. There is protrusion of the forehead and distortion of the maxillae, and obstruction of the respiratory passages results in stertorous respiration and dyspnea. The tip of the tongue usually protrudes from the mouth, and the eyes bulge. There is some variation between affected animals in their appearance at birth. In most cases the defects are as just described, but they become more exaggerated as the calf grows. In addition, abdominal enlargement and persistent bloat develop. The head is disproportionately large. The calves fail to grow normally and are about half the weight of normal calves of the same age.

The predominant form of the condition appears to be inherited as a simple recessive character, although the relationship of the “comprest” types to the total syndrome is more complex. Heterozygotes vary widely in conformation, but some of them show minor defects that may be attractive to cattle breeders who were seeking a chunkier, short-legged type of animal. For this reason, indiscriminate selection toward the heterozygote undoubtedly occurred, resulting in widespread dissemination of the character. Herefords and Aberdeen Angus are the breeds most commonly affected, but similar dwarfs occur also in Holstein and Shorthorn cattle, and typical dwarf animals have been produced by mating heterozygous Aberdeen Angus and Herefords. Besides the shortness of limbs, there is also a looseness of attachment of limbs and abnormal mobility of joints. The disorder of dolichocephalic long-nosed dwarfism in American Angus cattle is attributable to a nonsense mutation in exon 15 of cGMP-dependent type II protein kinase (PRKG2).

Ellis van Creveld syndrome (bovine chondrodysplastic dwarfism) occurs Grey Alpine cattle, Japanese Brown cattle, and

</tbody>
</table>

The defect is primarily chondrodystrophy rather than achondroplasia; the nasal bones and maxillae do not grow. Hydrocephalus develops because of the deformed cranium. In most breeds the condition is inherited as a simple recessive character, but a dominant form has occurred in Jerseys. The heterozygous form in Dexters is easily recognized by the shortness of the limbs. The heterozygote in other breeds is normal in appearance.

Miscellaneous Dwarfs
Other types of dwarfs have been described and include “comprest” and “compact” cattle in Herefords and Shorthorns and various other forms of proportional dwarfs. For example, in Charolais, miniature calves have been recorded that are exact replicas of normal calves but weigh only 5 to 16 kg at birth and are born 2 or more weeks prematurely. Most are dead at birth or die soon after so that the condition is effectively lethal. Proportional dwarfs occur also in Simmentals.

Inherited Congenital Achondroplasia With Hydrocephalus
First recorded as bulldog calves in Dexter cattle, this inherited defect has since been observed in a variety of forms in other breeds, including Jerseys, Guernseys, Holsteins, and Japanese Brown cattle. Chondrodysplasia in the Holstein–Friesian breed sharing morphologic features with the Dexter bulldog calves have been reported from the United States, the Netherlands, Great Britain, and recently in Denmark. Dexter bulldog–type calves have occurred in French and Danish Holstein calves in a familial pattern related to the sire Igale Masq, and it is likely that the genetic disorder is present in the Holstein breed worldwide.

Characteristic features of lethal chondrodysplasia (Dexter bulldog) calves in Australian Dexter cattle include abortion, disproportionate dwarfism, a short vertebral column, marked micromelia, a relatively large head with retruded muzzle, cleft palate, and abnormal protrusion of the tongue, and abomasum increase the chances of early death. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. These defects are lethal because the sheep are unable to graze properly.

REFERENCES

CONGENITAL OSTEOPETROSIS
Osteopetrosis is a skeletal disorder of humans and animals characterized by the formation of overly dense bones. The disease is reported in Angus, Red Angus, Hereford, Simmental, and Holstein cattle.1 The inherited defect is recorded in Aberdeen Angus calves, which are stillborn and undersized. The major manifestations are shortening of the mandible with protrusion of the tongue, impaction of the lower molars, a patent fontanelle, and the characteristic lesion of shortness of the long bones and absence of a marrow cavity in them. The absence of the marrow cavity, caused by defective remodeling of the bone, gives it a homogeneous shaft, leading to the colloquial name of “marble bone.” Genetically affected calves are typically aborted late in gestation, display skull deformities, and exhibit a marked reduction of osteoclasts. The disease is caused by a deletion mutation within bovine SLC4A2,2 encoding an anion exchanger protein, causing loss of SLC4A2 function that induces premature cell death and likely results in cytoplasmic alkalinization of osteoclasts, which, in turn, may disrupt acidification of resorption lacunae.

INHERITED PROBATOCEPHALY (SHEEPSHEAD)
This defect is inherited in Limousin cattle. The cranial bones are deformed so that the head resembles that of a sheep. The accompanying defects in the heart, buccal cavity, tongue, and abomasum increase the chances of an early death.

INHERITED ATLANTO-OCCIPITAL DEFORMITY
(See “Congenital Defects of the Nervous System.”)

INHERITED AGNATHIA
Partial or complete absence of the mandibles with ventral displacement of the ears occurs in sheep and is categorized as a lethal recessive because the sheep are unable to graze properly.

INHERITED DISPLACED MOLAR TEETH
Inherited as a simple recessive character, the defect of displaced molar teeth usually results in the death of affected calves within the first week of life. The six premolars of the lower jaw are impacted or erupted in abnormal positions, often at grotesque angles. The mandible is shorter and narrower than normal. There is no abnormality of the incisors or upper jaw.

INHERITED JAW MALAPPOSITION
Defective apposition of upper and lower incisors, or lower incisors and dental pad, in ruminants may result in inefficient grazing and malnutrition. Abnormal protrusion of the mandible (mandibular prognathism) is of most importance in ruminants, and there is good evidence that abnormal length of the mandible is inherited. Among British breeds of cattle the defect is more common in beef than in dairy breeds. In Herefords and Angus the inheritance is thought to be conditioned by a single recessive gene.

Brachygnathia, underdevelopment of the mandible, has also been recorded in Dairy Shorthorn, Jersey, Holstein, Ayrshire, and Simmental cattle, with the defect so severe in some cases that the animals are unable to suck. In Angus cattle, brachygnathia can occur linked to a generalized degenerative joint disease, in which all joint surfaces are involved. Affected animals,
detected at a few days to 4 months of age, are not viable. Inheritance of the defect is probably conditioned by a recessive gene.

A less severe degree of brachygnathia has been recorded in Merino and Rambouillet sheep. The mode of inheritance is suggested to be by the interaction of several pairs of genes. Brachygnathia occurs in Poll Merinos in Australia as part of the lethal brachygnathia, cardiomegaly, and renal hypoplasia syndrome. The disorder is also caused by intrauterine infection by the Schmallenburg virus.

Mandibular prognathism occurs as a part of other, more general defects, including achondroplastic dwarfism and inherited displaced molar teeth. It is associated with mutations in the MATN1 gene in donkeys.

Brachygnathia is also seen in horses but is not recognized as inherited. Maxillary virus.2 cerebral development with less pronounced hypoplasia, often associated with incomplete ossification of the upper limb joints. Spinal deformities, especially kyphoscoliosis, and cranial deformities, including a roman nose, deviation of the nose poll axis, and shortening of the mandible, are observed in some lambs (Fig. 15-16).

Inheritance by an autosomal-recessive gene with complete penetrance and variable expressivity has been established as the cause in Suffolks. The defect is thought to be one of deficiency of an insulin-like growth factor (IGF) and IGF–binding proteins. Differentiation from arthrogryposis-hydranencephaly is important because of the superficial similarity of the two diseases.

Inherited Chondrodysplasia in Texel Sheep
A chondrodysplasia resulting in a dwarfing phenotype has occurred in a Texel sheep flock as a newly recognized recessively inherited genetic disease of the Texel breed. The disorder in this breed is attributable to a 1-bp deletion of T (g.25513delT) at the 107bp position of exon 3 in the SLC13A1 gene (solute carrier family 13 [sodium/sulfate symporters], member 1). The mutation g.25513delT shifts the open reading frame of SLC13A1 to introduce a stop codon and truncate C-terminal amino acids. Heterozygotes appear clinically normal. Affected lambs appear normal at birth but show evidence of dwarfism, wide-based stance, and exercise intolerance as early as 1 week of age. Death usually occurs within 3 months, often after developing bilateral varus deformity of the forelimbs. Some severely affected lambs die with respiratory distress, probably as a result of tracheal collapse. Gross and microscopic lesions of variable severity were present in the tracheal, articular, epiphysial, and phyleal cartilage. In severe cases, articular cartilage in major joints was eroded from weight-bearing surfaces. The trachea was flaccid, was abnormally kinked, and had thickened cartilaginous rings and a narrow lumen. Affected sheep that survived to breeding age commonly developed severe degenerative joint disease. Histologically, chondrocytes were disorganized and surrounded by concentric rings of abnormal fibroblastic matrix, and the matrix often contained focal to coalescing areas of chondrolysis. The disease has considerable potential as a suitable model for studying various forms of therapy for human chondrodysplasia.

REFERENCES

INHERITED ARACHNOMELIA (INHERITED CHONDRODYSPLASIA)

Cattle
Arachnomenia, a suspected inherited disease of Simmental, Brown Swiss, Italian Brown calves, Fleckvieh, and other European breeds of cattle, is manifested by excessively long, thin limbs, and disproportionately long limbs. The bones are fragile, and there is curvature of the spine, foreshortening of the mandible, and associated cardiac and vascular defects. In Swiss Braunvieh cattle it is combined with arthrogryposis. The mutation is a 2-bp deletion mutation c.1224_1225delCA in exon 11 of the molybdenum cofactor biosynthesis protein 1 (MOCS1) gene in Simmental and Fleckvieh cattle, and a 1-bp insertion c.363–364insG in the sulfi de oxidase (SOUX) gene of Brown Swiss cattle. It is inherited as a simple recessive trait.

Sheep
Spider Lamb Syndrome
A hereditary chondrodysplasia is recorded in Suffolk and Hampshire lambs in which the limbs are thin and disproportionately long and have abnormal positions of the bones near the joints, causing abnormalities of posture. The disease is caused by a nonsynonymous T > A transversion in the highly conserved tyrosine kinase II domain of a positional candidate gene, fibroblast growth factor receptor 3 (FGFR3). The mutant FGFR3 allele has an additive effect on long-bone length, suggesting that the disease is not inherited as a strict monogenic, mendelian recessive trait but is determined primarily by the presence of the mutant FGFR3 allele and influenced by an animal’s genetic background. In contrast to FGFR3 mutations causing dwarfism in humans, this single-base change results in a skeletal overgrowth. There is also less muscle than normal. In severe cases the deformities are obvious at birth and may be lethal. In less severe cases the deformities do not become apparent until the lambs are several weeks old. The defects are readily visible in x-rays before clinical signs develop, and affected lambs can be detected in this way. The diagnostic lesion is multiple irregular islands of ossification in the upper limb joints. Spinal deformities, especially kyphoscoliosis, and cranial deformities, including a roman nose, deviation of the nose poll axis, and shortening of the mandible, are observed in some lambs (Fig. 15-16).

REFERENCES

INHERITED CRANIOSCHISIS (CRANIUM BIFIDUM)
The disease occurs in a number of pig breeds, but has been shown to be inherited only in Poland China pigs and their crossbreds. There is a deficit in the cranial bones, and meninges or encephalocoeles may result. The pigs are not viable. Genetic experiments have shown the inheritance to be of a recessive character with varying penetrance.

Many single cases of cranial and spinal deformity in farm animals have been likened to the human Arnold–Chiari malformation, but a specific syndrome of protrusion of the medulla oblongata and the cerebellum through the foramen magnum into the spinal canal has not been identified in a hereditary context in these species. Cases of cranium bifidum are reported on lambs and calves, but the inherited basis, if any, is unclear.

REFERENCES

INHERITED CRANIOFACIAL DEFORMITY
The defect is incompatible with life. One form in Border Leicester lambs is characterized by a variable degree of nasomaxillary hypoplasia, often associated with incomplete cerebral development with less pronounced sulci and gyri than normal. It appears to be inherited in a simple autosomal-recessive mode. A similar lethal defect is recorded in Angus cattle (as brachygnathia superior) in association with generalized degenerative joint disease.

Cyclopia (cyclops anomaly) is commonly associated with ingestion of plants, such as Veratrum californicum, containing cyclopamine, which is an inhibitor of the sonic hedgehog pathway. Cyclopia of other cause, or unknown cause, occurs sporadically.

REFERENCES
that requires that both the sire and the dam of an affected calf are carriers.

Most affected calves are born between day 250 and 285 of gestation. Approximately 80% of homozygous affected fetuses are aborted before gestation day 260. Birth weights are reduced. Most affected calves are stillborn, but affected calves occasionally are born alive. Euthanasia must be performed for humanitarian reasons.

In premature, stillborn, and neonatal affected calves, the defect is characterized by congenital growth retardation, malformed vertebrae, and tetramelic arthrogryposis. There is shortening of the cervical and thoracic parts of the vertebral column as a result of multiple hemivertebrae, fused and misshaped vertebrae, and scoliosis. Growth retardation and vertebral malformation are typical lesions. Malformation of the head, primarily in the form of dysplasia or palatoschisis, also occurs.

Symmetric flexures of the carpal and joints and the metacarpophalangeal joint in combination with a slight lateral rotation of the phalanges are also present. Similar low-grade arthrogryposis is present in the pelvic limbs. Heart defects were present in 50% of affected calves (interventricular septal defects, dextroposition of the aorta, and eccentric hypertrophy of the right ventricle).

Retrospective genotyping of affected calves according to the mutation in the \textit{SLC35A3} gene determined that there were homozygous affected, heterozygote, and homozygous normal genotypes. The morphologic expression of the malformation is wide, but certain aspects such as growth retardation, vertebral malformation, and symmetric arthrogryposis are nearly constant findings. A presumptive diagnosis of the malformation can be made in most cases based on necropsy findings combined with pedigree analysis and genotyping. Breeding studies were carried out in Denmark using selected cows that were progeny of sires with a heterozygous genotype for the malformation and were pregnant after insemination with semen from another sire with heterozygous malformation genotype. The number of calves born with the malformation was less than expected, suggesting increased intrauterine mortality. Fertility traits in Holsteins are severely affected by the malformation phenotype of the fetus. If the fetus is homozygous for the malformation, 29% of the cows will abort before gestation day 100, increasing to 45% at day 150 and 77% at day 260. Rates of nonreturn to service, frequency of calvings after the first insemination, and interval from insemination to next calving were significantly reduced by a fetal malformation phenotype.

Pedigree analysis and DNA analyses of semen from sires used for insemination have found a widely branched familial occurrence of the malformation in the Holstein breed.

**COMPLEX VERTEBRAL MALFORMATION IN HOLSTEIN CALVES**

A lethal congenital defect of the axial skeleton of purebred Holstein calves has been reported in Denmark, the United States, and the United Kingdom. It is caused by a mutation in the gene \textit{SLC35A3} coding a uridine-diphosphate-N-acetylglucosamine transporter. A single-base transversion of guanine to thymine has been located in the abnormal allele at position 559. It is present in both copies of the allele, and the mutation is lethal. It is a simple recessive genetic defect
The mutation in the SCL35A3 gene has been traced to the U.S. sire Penstate Ivanhoe Star, born in 1963, and his widely used son Carlin-M Ivanhoe Bell, born in 1974. Descendants of this bull in China have a heterozygote carrier frequency of 9.54% and 16.7% in Poland. The frequency of carriers in Giroldano dairy cattle in Brazil is less than 2%. The malformation mutation is not restricted to descendants of the American Holstein–Friesian bull Carlin-M Ivanhoe Bell. Through these sires and elite sires genetically related to them, the defect has been disseminated in the Holstein breed worldwide. PCR testing is available to detect heterozygotes. Testing is available on registered or registerable Holstein animals only through the Holstein Association (Holstein USA), through one of the National Association of Animal Breeders’ member AI organizations, or at the Van Haeringen Laboratorium, Wageningen, the Netherlands.

**REFERENCES**

**INHERITED REDUCED PHALANGES (AMPUTATES, ACROTERIASIS, ECTROMELIA)**

The defect of inherited reduced phalanges has been recorded in cattle and appears to be inherited as a single recessive character. The limbs are normal down to the metacarpal and metatarsal bones, which are shorter than usual, but the first two phalanges are missing, and the normal hooves and third phalanges are connected to the rest of the limb by soft tissues only. The calves are unable to stand but can crawl about on their knees and hocks.

**Hereditary Hemimelia**

The bilateral absence of the distal half of the limb (e.g., the patella) and shortening or absence of the tibia, often accompanied by hydrocephalus, meningocoeles, ventral abdominal hernia, and cryptorchidism, comprise the syndrome known as tibial hemimelia. It is inherited in the Galloway breed of cattle. An autosomal-recessive mode of inheritance is assumed. A concerted program of eradicating the defect has been undertaken, based on test matings and examination for defects of 90-day fetuses obtained by terminating pregnancy with prostaglandin. Hemimelia and amelia also occur in sheep.

**Hereditary Peromelia of Mohair Goats**

The syndrome of hereditary peromelia of mohair goats includes agenesis of the phalanges and parts of the metacarpus and metatarsus affecting one or more limbs; it follows an autosomal-recessive mode of inheritance.

**Amputates**

An even more serious defect, in which the mandible and all the bones below the humerus and stifle are vestigial or absent, has been reported in British, French, and German Friesians. It appears to be conditioned by the inheritance of a single recessive gene. Similar “amputates” have been shown not to be inherited. The disease occurs in Italian buffalo, in which it is associated with chromosomal instability.

**REFERENCES**

**INHERITED MULTIPLE EXOSTOSIS**

Multiple exostosis affecting both cortical and medullary bone of the limbs and ribs has been described in Quarter horses and Thoroughbreds in the United States. The lesions are visible externally but cause little apparent inconvenience. It is inherited as a single autosomal-dominant gene. Restriction nuclease analysis is used to diagnose the disease.

**INHERITED CONGENITAL HYPEROSTOSIS (THICK FORELIMBS OF PIGS)**

This defect is thought to be caused by the inheritance of a simple recessive character. Affected piglets show obvious lesions at birth, and although many of them die or are destroyed immediately, a proportion of them may survive. The forelimbs are markedly enlarged below the elbows, and the skin is tense and may be discolored. There is difficulty in standing and moving about, and starvation and crushing contribute to the mortality rate. There is extensive edema of the subcutaneous tissues, thickening of the bones, and roughness of the periosteum. It is thought that the primary lesion is a separation of the periosteum from the bone.

**INHERITED RICKETS**

An inherited form of rickets occurs in purebred Corriedale sheep in New Zealand, with an incidence of up to 20 lambs out of 1600 over a 2-year period. Affected sheep have decreased growth rate, thoracic lordosis, and angular limb deformities, with low serum calcium and phosphate concentrations and normal 25 hydroxyvitamin D and 1,25 dihydroxyvitamin D$_3$ concentrations. The disease is inherited as a simple autosomal-recessive disorder caused by a nonsense 250C/T mutation on exon 6 in the dentin matrix protein I gene (DMP1). This mutation introduces a stop codon (R145X) and could truncate C-terminal amino acids. Affected sheep are “T T” genotypes, carriers are “C T”, phenotypically normal related sheep are either “C T” or “C C,” and unrelated normal sheep from other breeds are “C C.” A simple diagnostic test can identify carriers with the defective “T” allele. Necropsy examination reveals segmental thickening of physis, growth-arrest lines, collapse of subchondral bone of the humeral head, thickened cortices, and enthesophytes around distal limb joints. Other features include hypertrophic chondrocytes at sites of
endochondral ossification; inappropriate and excessive osteoclastic resorption; microfractures; and wide, unmineralized osteoid seams lining trabeculae and filling secondary osteons.3 The disease of pigs is indistinguishable from rickets as a result of nutritional inadequacy.4 The pigs are healthy at birth. Subsequently there is hypocalcemia, hypophosphatemia, and increased serum alkaline phosphatase activity. The defect is a failure of active transport of calcium through the wall of the small intestine.

REFERENCES

INHERITED TAILLESSNESS AND TAIL DEFORMITY
Complete absence of the tail or deformity of the appendage occur relatively commonly as a congenital defect. The disease “crooked-tail syndrome” in Belgian Blue cattle is attributable to a loss-of-function mutation of the bovine MRC2 gene that impairs production of Endo18 protein. Affected cattle have signs of impaired endochondral ossification and skeletal and muscular malformations. The mutation is also associated with muscular attributes in heterozygotes, including double muscling (as a result of a defect in the myostatin gene), that are desirable traits and result in 25% of Belgian Blue cattle being carriers for the condition.1

A syndrome of vertebral and spinal dysplasia occurs in Holstein cattle. There are tail malformations and neurologic dysfunction, with gait abnormalities of the hindlimbs. The deformities and neurologic dysfunctions vary from subtle or mild (limited to tail deformities) to paraparesis. The syndrome is inherited in a dominant mode with incomplete penetrance.2

REFERENCES

CONGENITAL CHONDRODYSTROPHY OF UNKnown ORIGIN (CCUO, “ACORN” CALVES, CONGENITAL JOINT LAXITY AND DWARFISM, CONGENITAL SPINAL STENOSIS)
A noninherited condition has been described in the United States, Europe, Africa, Australia, and New Zealand that resembles inherited dwarfism.4 The disease occurs in poor-range areas and is thought to be attributable to a maternal nutritional deficiency during the middle trimester of pregnancy.5 The specific dietary factors involved have not been determined.

Cases are characterized by damage to physical growth plates with subsequent failure of growth of long bones. Abnormal osseous development of the head causes superior brachygnathia. Shortening of the shafts of the long bones of the limbs is accompanied by rotated limbs and bending at the joints, and calves nurse and stand with difficulty. Deformities of the nasal turbinates and trachea are often present and frequently lead to breathing difficulties. Incoordination, arching of the back, and a tendency to bloat, which may cause death, also occur. The dentition is normal. Muscle spasticity, wry neck, circling, falling backward, and goose-stepping occur rarely. Serologic results for Akabane virus, Aino virus, bovine virus diarrhea virus, and Bluetoongue are typically negative.6 Most of the calves are born alive; in badly affected herds, as many as 15% of calves may be affected. The original name for the condition (Acorn calves) was derived from the common occurrence of acorns in the diet of affected herds, although the acorns are not thought to have any etiologic significance. Currently, an unknown nutritional deficiency or deficiencies, possibly including manganese,7 during the second trimester is thought to be the cause.

Inherited Diseases of Joints

INHERITED ARTHROGYROSIS (INHERITED MULTIPLE TENDON CONTRACTURE)
Inherited fixation of limb joints present at birth is recorded in many breeds of cattle, especially in Belgian Blue, Shorthorn, Charolais, Piedmont, and Swedish Dole. It is inherited as a simple recessive mutation in the PIGF gene in Belgian Blue cattle. It is inherited as a single recessive mutation in the PIGF gene in Belgian Blue cattle.9 The disease occurs in Swiss Large White pigs as part of the arthrogryposis multiplex congenita complex of clinical abnormalities that includes inferior brachygnathism and spinal curvature.9

There are many environmental causes of the disease, the most well recognized of which are Schmallenberg and Akabane virus infection of early pregnancy (discussed under that heading).3

Simple Arthrogryposis
The limbs of affected calves are fixed in flexion or extension and cause dystocia as a result of abnormal positioning and lack of flexibility. There is no involvement of joint surfaces, and the joints can be freed by cutting the surrounding tendons or muscles. There is atrophy of limb muscles, and those calves that are born alive are unable to stand and usually die or are destroyed within a few days.

Arthrogryposis With Dental Dysplasia
Arthrogryposis with dental dysplasia in cattle appears to be inherited in a dominant manner. The teeth are soft, fleshy, and easy to bend. There is no defect of bones or joints other than marked softness and the presence of excess cartilage at the epiphyses. There is abnormal ossification of the cartilage. The calves are of normal size, do not cause dystocia, and, although they are unable to stand because of the excessive flexibility of the limbs, they can suck. Hypostatic pneumonia usually develops and causes death of the calf.

Arthrogryposis With Palatoschisis
Arthrogryposis with palatoschisis (SAP) is inherited as a simple recessive trait with low penetrance in pure French Charolais in France and high penetrance in 7/8 Charolais cattle in Canada, where the gene frequency is high in purebred and crossbred Charolais. Among crossbred Charolais the homozygous condition is almost always markedly expressed and lethal, but a high percentage of purebred homozygous cattle show slight to no visible effect of the gene and survive. Because of the low rate of prevalence in France, attempted eradication does not appear to be economical.

In this syndrome all limbs are usually affected but the front limbs more than the hindlimbs, and the more distal joints are more rigidly fixed than proximal ones. The muscles of affected limbs are atrophic and pale in color. Histologic changes in the spinal cord suggest that the muscle atrophy is neurogenic. In affected calves the gestation period may be longer than normal by an average of 2 weeks.

Arthrogryposis With Multiple Defects
In Simmentals a combined set of defects includes arthrogryposis, often with the limbs in a wraparound position around the body, underdevelopment of the mandible, curvature of the spine, and defects of the heart and main vessels.

Arthrogryposis in Species Other Than Cattle
Inherited arthrogryposis has also been recorded in Merino and Corriedale sheep and in Norwegian Landrace pigs, in which it is thought to be inherited as a simple recessive trait. The Corriedale defect is associated with other lesions, including brachygnathism inferior, hydranencephaly, and thoracic scoliosis. Inherited arthrogryposis in pedigree Suffolk lambs has been described.1 Breeding studies using superovulation and embryo transfer were used to increase the numbers...
of offspring from females that were carrying the gene or genes responsible for the defect, which is inherited as an autosomal-recessive trait.

Ovine heritable arthrogryposis multiplex congenita is a congenital syndrome in lambs characterized by curvature, hunching, and twisting of the thoracic spine, with associated abnormalities of the ribs and sternum, distal arthrogryposis of the carpal and tarsal joints, and cleft hard and soft palate or palatoschisis (a median fissure of the palate) and is an autosomal-recessive inherited disease. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion, and there is some curvature of the spine. Fetal dystocia always occurs, and embryotomy or cesarean section is necessary to deliver the calf.

Ankylosis of limb joints combined with cleft palate occurs occasionally in Charolais cattle and is suspected of being inherited. Ankylosis of the coffin joint, developing at several weeks of age, has been reported in Simmental calves. The etiology of the condition is not clear.

INHERITED MULTIPLE ANKYLOSES

Multiple ankylosis affecting all limb joints has been recorded as an inherited congenital defect of Holstein calves. The abdomen of the dam shows marked enlargement at month 6 to 7 of pregnancy, and this may occasion some respiratory distress. Excessive fetal fluids are present, and insertion of the hand per rectum is impeded by the distended uterus. Abortion during the last month of pregnancy is a common occurrence. Affected fetuses have a very short neck, ankylosed intervertebral joints, and varying degrees of ankylosis of all limb joints. The limbs are fixed in flexion, and there is some curvature of the spine. Fetal dystocia always occurs, and embryotomy or cesarean section is necessary to deliver the calf.

REFERENCES

INHERITED PATELLAR SUBLUXATION

Unilateral or bilateral subluxation occurs as an inherited defect in Bos indicus cattle and in water buffalo (Bubalus bubalis). Shetland ponies also have a predisposition, and a monogenic autosomal-recessive transmission is suspected. There is periodic lameness, with the affected limb held in rigid extension; the patella is displaced medially.

REFERENCES

INHERITED HYPERMOBILITY (LAXITY) OF JOINTS

Inherited hypermobility of joints is recorded only in Jersey cattle. It has assumed great importance because of the great popularity of a sire that carried the gene. There is abnormal flexure and extension of all joints but especially the hock, stifle, hip, knee, elbow, and shoulder joints. The muscles are much atrophied, and the joints look very enlarged as a result. It is impossible for the calves to stand, but they are bright, alert, and eat well. The limbs are so flexible that they can be bent into extraordinary positions and almost tied in knots. A drawer sign, a displacement of the articular surfaces laterally, produced by manual pressure, can be elicited easily and with a displacement of up to 2 cm. There are no detectable lesions in the nervous or musculoskeletal systems. Although the disease is known to be inherited as a simple autosomal-recessive trait, it has also been seen in circumstances that preclude inheritance being the cause.

INHERITED HIP DYSPLASIA

An inherited defective development of the acetabulum occurs in Doel horses. There is no clinical evidence of the disease at birth, but osteoarthritis of the joint and disruption of the round ligament develop subsequently. Hip dysplasia occurs in Belgian Blue cattle.

The major functions of the skin are:

- To maintain a normal body temperature
- To maintain a normal fluid and electrolyte balance within the animal
- To create a mechanical barrier to protect the body from noxious agents and organisms
- To act as a sensory organ perceiving those features of the environment that are important to the subject's survival

In general, these functions are not greatly impaired by most diseases of the skin of large animals, with the exceptions of failure of the sweating mechanism, which does seriously interfere with body temperature regulation, and severe burns or other skin trauma, which may cause fatal fluid and electrolyte loss.

The major effects of skin diseases in large animals are esthetic and economic but can also present a considerable animal welfare concern. Discomfort and scratching interfere with normal rest and feeding, and when the lips are affected, there may be interference with prehension. The unsightly appearance of the animal distresses the owner. There is loss of the economic coat, and the value and acceptability of animals for transportation and appearance in exhibitions is greatly reduced.

Primary/Secondary Lesions

Diseases of the skin may be primary or secondary in origin. In primary skin disease the lesions are restricted initially to the skin, although they may subsequently spread from the skin to involve other organs. Conversely, cutaneous lesions may be secondary to disease originating in other organs. Differentiation between primary and secondary skin diseases should be attempted by seeking evidence that organs other than the skin are affected. If there is no such evidence produced during a thorough clinical examination of the patient, it is reasonable to assume that the disease is primary. Even if involvement of other organs is diagnosed, it is still necessary to determine whether the involvement constitutes the primary state or whether it has developed secondarily to the skin disease. This decision can be based on the chronology of the signs, elicited by careful history taking, and a detailed knowledge of the individual diseases likely to be encountered.

Taking an accurate anamnesis and doing a complete clinical examination must precede the careful examination of the skin itself, using the proper technique of examination. The veterinarian may need to employ advanced diagnostic procedures such as histopathological examination of a biopsy specimen to define the type of lesion present.

The purpose of this chapter is to describe the basic skin lesions so that the differential diagnosis, up to the point of defining the type and nature of the lesion, the pathoanatomical diagnosis, can be accomplished. A definitive etiologic diagnosis requires further examination and is included in the discussion of the specific diseases.

Clinical Signs and Special Examination

A general clinical examination is followed by a special examination of the skin and must include inspection and, in most cases, palpation. Additional information can be obtained by taking swabs for bacteriologic examinations, scrapings for examination of dermatophytes and metazoon parasites, and biopsy for histopathological examination.

Biopsy material should include abnormal, marginal, and normal skin. Artifacts are common in biopsy specimens, including nonrepresentative sampling, crushing the specimen by forceps or hemostat, and inadequate fixation.

A Wood’s lamp finds a special use in the examination of the skin for dermatophytes.

Descriptions of lesions should include size, depth to which they penetrate, topographic distribution on the body, and size of the area affected. Abnormalities of sebaceous and sweat secretion, changes in the hair or wool coat, and alterations in color and temperature of the skin should be noted, as should the presence or absence of pain or pruritus.

Lesions

An accurate definition of the lesions, summarized in Table 16-1, is an essential part of a dermatologic patient’s clinical record. The table makes a primary differentiation into discrete and diffuse lesions, and these categories need to be further categorized in terms of...
of size (e.g., they may be limited diffuse lesions or extensive localized ones).

**Abnormal Coloration**

The parameter of abnormal coloration includes jaundice, pallor, and erythema. In animals these conditions are rarely visible in light-colored skins. Red–purple discoloration of the skin of septicemic, white pigs may be dramatic, but no diagnostic significance can be attached to its degree. Early erythema is a common finding where more definite skin lesions are to develop, as in early photosensitization. The blue coloration of early gangrene (e.g., of the udder and teat skin in the early stages of peracute bovine mastitis associated with *Staphylococcus aureus*) is characterized by coldness and loss of elasticity.

Hypopigmentation of the skin may be general, as in albino, pseudoalbino, and lethal white animals. Local patches of hypopigmentation are characteristic of vitiligo and leukoderma.

**Pruritus**

- **Pruritus or itching** is the sensation that gives rise to scratching.
- **Hyperesthesia** is increased sensitivity to normal stimuli.
- **Paresthesia** is perverted sensation, a subjective sensation, and not diagnosed in animals.

Secretion Abnormalities of Skin Glands

The activity of the sweat glands is controlled by the sympathetic nervous system and is for the most part a reflection of body temperature. Excitement and pain may cause sweating as a result of cerebral cortical activity. A generalized form of hyperhidrosis, apparently inherited, has been recorded in Short-horn calves. Local areas of increased or decreased sweating may arise from peripheral nerve lesions or obstruction of sweat gland ducts. A generalized anhidrosis is recorded in horses and occasionally in cattle.

Excess secretion of sebum by sebaceous glands causes oiliness of the skin or seborrhea, but its pathogenesis is poorly understood.

Abnormalities of Wool and Hair Fibers

Deficiency of hair or wool in comparison to the normal pilosity of the skin area is alopecia or hypotrichosis. Hirsutism, abnormal hairiness, manifested by a long, shaggy, and usually curly coat, is most common in aged ponies with adenomas of the pars intermedia of the pituitary gland.

The character of the fiber may also vary with variations in the internal environment. For example, in copper deficiency the crimp of fine wool fibers is lost, and the wool becomes straight and "steely." Alternation in coat color, achromotrichia, may be generalized or segmental along the fiber.

Principles of Treatment of Diseases of the Skin

PRIMARY TREATMENT

For a specific treatment, accurate diagnosis of the condition and the identification of underlying cause must precede the selection of any topical or systemic treatment. Hair coat and debris on and around the affected area must be removed to enable topical applications to come into direct contact with the affected skin. In bacterial diseases susceptibility tests on cultures of the organism are advisable. Bacterial resistance to antimicrobials used in veterinary dermatologic practice is a concern. The uncritical use of antimicrobials either locally or systemically should be avoided to contain the development of bacterial resistance to microbials.

Specific skin diseases caused by bacteria, fungi, and metazoan parasites are reasonably amenable to treatment with the appropriate specific remedy. Identification of the fungal or parasitic organism presumably causing the disease allows for selection of a pharmacologic substance and route of administration with documented efficacy against the agent in question and can prevent frustrating treatment failures.

Removal of the causative agent in allergic diseases and photosensitization may be impossible, and symptomatic treatment may be the only practicable solution. Symptomatic treatment may also be indicated for welfare reasons in cases where the underlying cause of the disorder could not (yet) be identified. The veterinarian must be aware that in these cases antiinflammatory treatment, although indicated, may complicate further diagnostic workup. In some instances the primary disease may be confounded by the presence of a secondary agent, which can lead to confusion in diagnosis.

SUPPORTIVE TREATMENT

Supportive treatment may include prevention of secondary infection by the use of bacteriostatic ointments or dressings and the prevention of further damage from scratching.

- Effective treatment of pruritus depends on the reduction of central perception of itch sensations by the use of antihistaminic, sedative, or narcotic drugs administered systematically or on successful restraint of the mediator between the lesion and the sensory end organ. In the absence of accurate knowledge of the pathogenesis of pain, it is usual to resort to local anesthetic agents, which are short-lived in their activity, and corticosteroids, which are longer-acting and effective, provided that vascular engorgement is part of the pruritus-stimulating mechanism.
- When large areas of skin are involved, it is important to prevent the absorption of toxic products by continuous irrigation or the application of absorptive dressings. Losses of fluid and electrolytes should be compensated by oral or parenteral administration of fluids containing the necessary electrolytes.
- Ensure an adequate dietary intake of protein, particularly sulfur-containing amino acids, to facilitate the repair of skin tissues.
- Boredom contributes significantly to an animal’s response to itch stimuli, and close confinement of affected animals is best avoided.

Diseases of the Epidermis and Dermis

PITYRIASIS

Primary pityriasis is characterized by excessive bran-like scales on the skin and is caused...
by overproduction of keratinized epithelial cells. The etiology is uncertain. The diagnosis is based on clinical presentation and can be supported by further diagnostic testing ruling out other differential diagnoses. Proposed causative or predisposing factors are as follows:

- Hypovitaminosis A
- Nutritional deficiency of B vitamins, especially of riboflavin and nicotinic acid, in pigs, or linolenic acid, and probably other essential unsaturated fatty acids
- Poisoning by iodine

Secondary pityriasis is characterized by excessive desquamation of epithelial cells and usually associated with the following:

- Scratching in flea, louse, and mange infestations
- Keratolytic infection (e.g., with ringworm fungus)

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the hair follicles and spreads to the surrounding stratum corneum.

Primary pityriasis scales are superficial, accumulate where the coat is long, and are usually associated with a dry, lusterless coat. Itching or other skin lesions are not features. Secondary pityriasis is usually accompanied by the lesions of the primary disease.

Pityriasis rosea or pustular psoriasisform dermatitis is a skin condition of piglets that is clinically and histopathologically distinct from human pityriasis rosea (see also “Pityriasis rosea”). Pityriasis is identified by the absence of parasites and fungi in skin scrapings.

**DIFFERENTIAL DIAGNOSIS**

- Hyperkeratosis (see following discussion)
- Parakeratosis (see following discussion)
- Swine erysipelas (for pityriasis rosea in pigs)
- Porcine dermatitis and nephropathy syndrome (for pityriasis rosea in pigs)
- Ringworm (for pityriasis rosea in pigs)

**TREATMENT**

Primary treatment requires correction of the primary cause. Supportive treatment commences with a thorough washing, followed by alternating applications of a bland emollient ointment and an alcoholic lotion. Salicylic acid is frequently incorporated into a lotion or ointment with a lanolin base.

**HYPERKERATOSIS**

Epithelial cells accumulate on the skin as a result of excessive keratinization of epithelial cells and intercellular bridges, interference with normal cell division in the granular layer of the epidermis, and hypertrophy of the stratum corneum.

Local hyperkeratosis may be caused by the following:

- Mechanical stress on pressure points (e.g., elbows, hocks, or brisket) when animals lie habitually on hard surfaces
- Mechanical and/or chemical stress (e.g., **teat-end keratosis** of dairy cows that can be caused by improper milking machine settings, overmilking, improper use of teat sanitizers or cold weather)
- Parasitism (e.g., hyperkeratotic form of sarcoptes mange of pigs and small ruminants)

Generalized hyperkeratosis may be caused by the following:

- Poisoning with highly chlorinated naphthalene compounds
- Chronic arsenic poisoning
- Inherited congenital ichthyosis
- Inherited dyserthropoiesis–dykeratosis
- Infection with *Sporothrix schenckii*, a fungus, was recently associated with generalized hyperkeratosis in a calf and a goat kid.

The skin is dry, scaly, thicker than normal, usually corrugated, hairless, and fissured in a gridlike pattern. Secondary infection of deep fissures may occur if the area is continually wet. However, the lesion is usually dry, and the plugs of hyperkeratotic material can be removed, leaving the underlying skin intact. Confirmation of the diagnosis is by the demonstration of the characteristically thickened stratum corneum in a biopsy section, which also serves to differentiate the condition from parakeratosis (see also “Parakeratosis”) and inherited ichthyosis (see also “Congenital and Inherited Skin Defects”). Primary treatment depends on correction of the cause. Supportive treatment is by the application of a keratolytic agent (e.g., salicylic acid ointment).

**REFERENCES**

**PARAKERATOSIS**

Parakeratosis, a skin condition characterized by incomplete keratinization of epithelial cells, can have various causes:

- Caused by nonspecific chronic inflammation of cellular epidermis
- Associated with dietary deficiency of zinc
- Part of an inherited disease (described later in the chapter)

The initial lesion comprises edema of the prickle cell layer, dilatation of the intercellular lymphatics, and leukocyte infiltration. Imperfect keratinization of epithelial cells at the granular layer of the epidermis follows, and the horn cells produced are sticky and soft, retain their nuclei, and stick together to form large masses, which stay fixed to the underlying tissues or are shed as thick scales. The lesions may be extensive and diffuse but are often confined to the flexor aspects of joints (referred to historically in horses as **mallerds** and **sallenders**). Initially the skin is reddened, followed by thickening and gray discoloration. Large, soft scales accumulate, are often held in place by hairs, and usually crack and fissure; their removal leaves a raw, red surface. Hyperkeratosis scales are thin and dry and accompany an intact, normal skin.

Parakeratosis in pigs is most commonly seen in swine 2 to 4 months of age and responds to dietary supplementation of zinc. Zinc deficiency in affected animals can be absolute or relative. The latter can be caused by excessive dietary calcium or phytic acid content or by a deficiency in essential fatty acids, which all interfere with the intestinal absorption of zinc.

The diagnosis is made based on the clinical presentation and can be confirmed by the identification of imperfect keratinization in a histopathological examination of a biopsy or a skin section at necropsy.

**DIFFERENTIAL DIAGNOSIS**

- Hyperkeratosis
- Pachyderma
- Ringworm
- Sarcoptic mange
- Greasy pig disease (*Staphylococcus hyicus* infection)
- Inherited ichthyosis
- Inherited parakeratosis of calves
- Inherited dermatosis vegetans in pigs
- Inherited epidermal dysplasia

**TREATMENT**

Primary treatment requires correction of any nutritional deficiency (specifically, correcting zinc and preventing excessive dietary calcium content).

Supportive treatment includes removal of the crusts by the use of keratolytic agent (e.g., salicylic acid ointment) or by vigorous scrubbing with soapy water, followed by application of an astrigent (e.g., white lotion paste), which must be applied frequently and for some time after the lesions have disappeared.

**PACHYDERMA**

Pachyderma, including scleroderma, is thickening of the skin affecting all layers, often including subcutaneous tissue, and usually localized but often extensive, as in lymphangitis and greasy heel in horses. There are no specific causes, with most cases being a result of a nonspecific chronic or recurrent inflammation.
In affected areas the hair coat is thin or absent, and the skin is thicker and tougher than usual. It appears tight and, because of its thickness and reduced volume of subcutaneous tissue, cannot be picked into folds or moved easily over underlying tissue. The skin surface is unbroken, and there are no lesions and no crusts or scabs as in parakeratosis and hyperkeratosis.

Confirmation of the diagnosis depends on histopathological examination of a biopsy. The cells in all layers are usually normal, but the individual layers are increased in thickness. There is hypertrophy of the prickle cell layer of the epidermis and enlargement of the interpalillary processes.

### DIFFERENTIAL DIAGNOSIS
- Parakeratosis
- Cutaneous neoplasia
- Papillomatosis

### TREATMENT
**Primary treatment** requires removal of the causal irritation, but in well-established cases little improvement can be anticipated, and surgical removal may be a practical solution when the area is small. In early cases local or systemic corticosteroids may effect a recovery.

### IMPETIGO
Impetigo is a superficial eruption of thin-walled, small vesicles, surrounded by a zone of erythema, that develop into pustules, then rupture to form scabs.

In humans, impetigo is specifically a streptococcal infection, but lesions are often invaded secondarily by *staphylococci*. In animals the main organism found is usually a staphylococcus. The causative organism appears to gain entry through minor abrasions, with spread resulting from rupture of lesions causing contamination of surrounding skin and the development of secondary lesions. Spread from animal to animal occurs readily.

Two specific examples of impetigo in large animals are as follows:
- **Udder impetigo** (udder acne) of cows
- **Contagious impetigo**, also known as *exudative epidermitis* (see also “Udder Impetigo”) or “greasy pig disease,” caused by *Staphylococcus hyicus* (see also “Exudative Epidermitis/Greasy Pig Disease”)

Confirmation of the diagnosis is by isolation of *staphylococci* from vesicular fluid.

### DIFFERENTIAL DIAGNOSIS
- Cowpox/buffalopox, in which the lesions occur almost exclusively on the teats and

### TREATMENT
**Primary treatment** with antibiotic topically is usually all that is required because individual lesions heal so rapidly (see also under “Greasy Pig Disease”).

**Supportive treatment** is aimed at preventing the occurrence of secondary lesions and spread of the disease to other animals. Twice-daily bathing with an efficient germicidal skin wash is usually adequate.

### URTICARIA
Urticaria (hives) is a skin condition characterized by development of topical dermal edema becoming apparent as cutaneous wheals. Horses are the most commonly affected species. In acute cases hives appear suddenly and regress within hours. Longer-lasting or even chronic cases are characterized by the continuous recurrence of new wheals on the skin for days or even months. Urticaria can occur as localized allergic reaction only affecting parts of the skin or as part of a more severe systemic allergic reaction.

### ETIOLOGY
Although urticaria in many cases is of allergic origin, nonallergic causes such as physical stress on the skin (e.g., through squeezing [pressure urticaria or dermatographism] or exposure to low ambient temperature [cold urticaria]) can result in the development of urticaria.

In horses chronic urticaria is most commonly associated with feed allergies. Specifically, in some of the chronic and recurrent cases a causative allergen cannot be found and the underlying etiology remains obscure. In humans the presence of serum immunoglobulin G (IgG) autoantibodies targeting immunoglobulin E (IgE) or the IgE receptor has been documented in a subset of patients with chronic urticaria of unknown etiology. An autoimmune basis for chronic urticaria has therefore been proposed.

**Primary urticaria** can be caused by the following:
- Insect stings
- Contact with stinging plants
- Ingestion of unusual food, with the allergen, usually a protein
- Occasionally an unusual feed item (e.g., garlic to a horse)

**Secondaries** can occur almost exclusively on the teats and

### PATHOGENESIS
Degranulation of mast cells releasing chemical mediators of inflammation that result in the subsequent development of dermal edema. Horses with an allergic trend predispose the animal to the development of urticaria. A primary dilatation of capillaries causes cutaneous erythema. Edema from the damaged capillary walls causes local edema in the dermis, and a wheal develops. Only the dermis, and sometimes the epidermis, is involved. In extreme cases the wheals may expand to become seromas, when they may ulcerate and discharge. The lesions of urticaria usually resolve in 12 to 24 hours, but in recrudescent urticaria an affected horse may have persistent and chronic eruption of lesions over a period of days or months.

### CLINICAL FINDINGS
Wheels, mostly circular, well-delineated, steep-sided, easily visible elevations in the skin, appear very rapidly and often in large numbers, commencing usually on the neck but being most numerous on the body. They vary from 0.5 to 5 cm in diameter, with a flat top, and are tense to the touch. There is often no itching, except with plant or insect stings, and no discontinuity of the epithelial surface, exudation, or weeping. Pallor of the skin in affected areas is unbroken, and there are no itching, except with plant or insect stings, and no discontinuity of the epithelial surface.

**Secondary urticaria** occurs as part of a syndrome, such as the following:
- Respiratory tract infections in horses, including strangles and the upper respiratory tract viral infections
- Erysipelas in pigs
dermatographism, the production of a continuous wheal following the pattern of a blunt-pointed instrument drawn across the skin, can be demonstrated about 30 minutes later.

Urticaria lasting 8 weeks or longer is classified as chronic or recurrent urticaria, which may require testing for atopic disease using intradermal skin testing and serum testing for antigen-specific IgE.

Adverse reactions in dairy cattle following annual vaccination for foot-and-mouth disease are characterized by wheals (3 to 20 mm in diameter) covering most of the body, followed by exudative and necrotic dermatitis. The affected areas become hairless, and the wheals exude serum and become scabbed over. Edema of the legs is common, and vesicles occur on the teats. The lesions appear 8 to 12 weeks postvaccination and may persist for 3 to 5 weeks. Loss of body weight and lymphadenopathy also occur. Pruritus, depression, and a drop in milk yield are common. Adverse effects of parenteral administration of penicillin streptomycin in the form of a type I hypersensitivity reaction that was associated with rapid development of urticaria have been reported.3

**CLINICAL PATHOLOGY**

The diagnosis in most cases is based on the clinical presentation, possibly in combination with a history of local or systemic exposure to a potential allergen. Biopsies show that tissue histamine levels are increased, and there is a local accumulation of eosinophils. Blood histamine levels and eosinophil counts may also show transient elevation.

Opinions over the usefulness of intradermal skin tests in horses are strongly divided. Although intradermal testing may be of use in some cases, results are often difficult to interpret, and the panel of available allergens may not be the most appropriate for horses.4 Intradermal tests in horses without atopy and horses with atopic dermatitis or recurrent urticaria using environmental allergens indicate a greater number of positive reactions for intradermal tests in horses with atopic dermatitis or recurrent urticaria compared with horses without atopy. This provides evidence of type I IgE-mediated hypersensitivity for these diseases.

**Differential Diagnosis**

Differential diagnosis includes angioedema, though urticaria the lesions can be palpated in the skin itself. Angioedema involves the subcutaneous tissue rather than the skin, and the lesions are much larger and more diffuse. The two conditions may appear in the same animal at the same time.

**TREATMENT**

**Primary Treatment**

Spontaneous recovery is common in acute cases with incidental exposure to an allergen. In chronic or recurrent cases identification and removal of the allergen must be a priority. A change of diet and environment, especially exposure to the presumably causal insects or plants, is standard practice.

Supportive Treatment

Corticosteroids, antihistamines, or epinephrine by parenteral injection provides the best and most rational treatment, especially in the relief of the pruritus. One treatment is usually sufficient, but lesions may recur. The local application of cooling astringent lotions such as calamine or white lotion or a dilute solution of sodium bicarbonate is favored. In large animal practice parenteral injections of calcium salts are used, with apparently good results.

Long-term medical management of persistent/chronic urticaria involves the administration of corticosteroids and/or antihistamines. Oral administration or prednisone or prednisolone at the lowest possible dose on alternate days is the method of choice. The antihistamine of choice is oral hydroxyzine hydrochloride, initially at 1 to 2 mg/kg administered twice daily or three times daily, followed by gradual reduction to a minimum maintenance dose required to keep the horse free of lesions.

**REFERENCES**

**DERMATITIS AND DERMATOSIS**

**SYNOPSIS**

**Etiology**

Any disease of skin, including those characterized by inflammation. All pathogens, infectious, chemical, physical, allergic, autoimmune.

**Epidemiology**

Sporadic or outbreak; acute or chronic course; cosmetic to lethal; of most importance because of constraints on movement, sale, or exhibition; may affect animal welfare.

**Clinical signs**

Primarily localized to skin, including lesions varying from parakeratosis and pachyderma to weeping, through necrosis, vesicles, and edema. Secondary signs of shock, toxemia, anaphylaxis.

**Clinical pathology**

Positive findings in the area of skin swabs or scrapings.

**Necropsy lesions**

Inflammatory, degenerative, or vascular lesions in skin biopsy.

**Diagnostic confirmation**

Positive finding in skin biopsy.

**Treatment**

Primary treatment is removal of the (presumed) causative agent; supportive treatment includes treatment for pruritus, secondary infection, shock, toxemia, or fluid and electrolyte loss.

**ETIOLOGY**

Some of the identifiable occurrences of dermatitis in food animals and horses are as follows.

**All Species**

- Mycotic dermatitis as a result of *Dermatophilus congolensis*, in horses, cattle, and sheep
- *S. aureus*, a common finding in cases in all species, either as a sole pathogen or combined with other agents
- Ringworm
- Photosensitive dermatitis
- Chemical irritation (contact dermatitis) topically
- Arsenic—systemic poisoning
- Mange mite infestation—sarcoptic, psoroptic, choriotic, demodectic mange
Diseases of the Epidermis and Dermis

**Cattle**
- Udder impetigo (udder acne)—*Staphylococcus* spp.
- Udder clostridial dermatitis of cattle
- Dermatitis interdigitalis (see following discussion)
- Ulcerative mammillitis—udder and teats only
- Cutaneous botryomycosis of the udder caused by a combination of a trauma and infection by *Pseudomonas aeruginosa*
- Cowpox/buffalo pox
- Flexural seborrhea
- Lumpy skin disease of cattle—painful nodules (2 to 5 cm) develop over the entire body, caused by pox virus, serotype *lumpy skin disease virus* (LSDV)
- Foot-and-mouth disease—vesicles around natural orifices; vesicular stomatitis with lesions on teats and coronet
- Bovine virus diarrhea, bovine malignant catarrh, bluetongue—erose lesions around natural orifices, eyes, coronets
- Potato dermatitis in cattle, horses, and swine associated with prolonged feeding of potato distillery wastes; erythematous skin disease of distal limbs suspected to be of allergic origin
- Dermatitis as a result of the ingestion of *Vicia villosa* and *Vicia dasyacra*
- Bovine exfoliative dermatitis

**Sheep and Goats**
- Strawberry footrot—proliferative pustular dermatosis linked to spirochete-like organisms and *Dermatophilus* and *Rhizobium*
- Dermatophilosis (lumpy wool disease, rain scald)—*Dermatophilus congolensis*
- Fleece rot—constant wetting and associated with *Pseudomonas aeruginosa*
- Staphylococcal dermatitis—exudative dermatitis around eyes, ears, and base of horns in sheep; vesicles possibly present on teats and udder in goats
- Sheepox
- Contagious ecthyma—*Parapoxvirus* (Orf)
- Ulcerative dermatosis—caused by similar but antigenically distinct virus to Orf
- Rinderpest, peste des petits ruminants, bluetongue—as for cattle
- Foot-and-mouth disease and vesicular stomatitis
- Itch-mite (*Psorergates ovis*) infestation
- Blow-fly infestation (cutaneous myiasis)
- Elaeophoriasis (*Elaeophora spp.* infestation)
- Caprine idiopathic dermatitis
- Postdipping necrotic dermatitis (see following discussion).

**Horses**
- Staphylococcal pyoderma caused by *S. aureus/Staphylococcus intermedius*
- *Staphylococcus hyicus* in a syndrome reminiscent of greasy heel
- Dermatophytes, including ringworm, follicular dermatitis, hyphomycosis (pythiosis), tinea versicolor dermatitis
- Summer eczema (also Queensland or sweet itch)—sensitivity to *Calicoides* spp. sandflies
- Dermatophilosis/rain scald—*D. congolensis*
- *Actinomyces viscosum* causing skin pustules and nodules
- Horsepox
- Canadian horsepox
- Viral papular dermatitis (see following discussion)
- Vesicular stomatitis—vesicles around natural orifices
- Vesicular dermatitis around nasal area, eyes, and ears in horses stabled on shavings of a tree of the *Quassia* spp.
- Spongiosic vesicular dermatitis of unknown etiology
- Sporotrichosis
- Atopic dermatitis (IgE-mediated hypersensitivity)
- Chronic eosinophilic dermatitis (see following discussion)
- Pemphigus, lupus erythematosus, erythema multiforme, eosinophilic dermatitis and stomatitis (described separately in following discussion)
- Molluscum contagiosum (see following discussion)
- Linear hyperkeratosis (see following discussion)
- Nodular necrobiosis
- Equine aural plaque (see following discussion)
- Usain Gishu disease
- Cutaneous habronemiasis
- Equine tropical lichen (see following discussion)
- Midline ventral dermatitis as a result of infestation with *Hydracta irizans* (horn fly and buffalo fly)
- Trombidiiform mites, e.g., *Pyemotes tritic* and *Acarus (Tyroglyphus) farinae*
- Ulcerative dermatitis, thrombocytopenia and neutropenia in neonatal foals (see Aalloimmune hemolytic anemia of the newborn (neonatal isoerythrolysis, isoimmune hemolytic anemia of the newborn).

**Pigs**
- Ulcerative granuloma—*Borrelia suilla*
- Contagious epidermitis—*Staphylococcus hyicus* (‘greasy pig disease’)
- Pig pox
- Swine vesicular disease, vesicular exanthema of swine, foot-and-mouth disease—vesicles around natural orifices
- Contact with fresh parsnip tops, celery
- Sunburn
- Porcine necrotic ear syndrome (see following discussion)
- Nonspecific nutritional dermatitis—experimental nutritional deficiency of nicotinic acid, riboflavin, pantothenic acid, biotin
- Pityriasis rosea
- Idiopathic chronic recurrent dermatoses

**Special Local Dermatitides**
Special local dermatitides include dermatitis of the teats and udder, the bovine muzzle and coronet, and flexural seborrhea, and are dealt with under their respective headings.

**PATHOGENESIS**
Dermatitis is an inflammation of the deeper layers of the skin involving the blood vessels and lymphatics. The purely cellular layers of the epidermis are involved only secondarily. The noxious agent causes cellular damage, often to the point of necrosis, and, depending on the type of agent responsible, the resulting dermatitis varies in its manifestations. It may be acute or chronic, suppurrative, weeping, seborrheic, ulcerative, or gangrenous. In all cases there is increased thickness and increased temperature of the part. Pain or pruritus is present, and erythema is evident in unpigmented skin. Histologically there is vasodilatation and infiltration with leukocytes and cellular necrosis. These changes are much less marked in chronic dermatitis.

**CLINICAL FINDINGS**
Affected skin areas first show erythema and increased warmth. The subsequent stages vary according to the type and severity of the causative agent. There may be development of discrete vesicular lesions or diffuse weeping. Edema of the skin and subcutaneous tissues may occur in severe cases. The next stage may be the healing stage of scab formation; if the injury is more severe, there may be necrosis or even gangrene of the affected skin area. Spread of infection to subcutaneous tissues may result in a diffuse cellulitis or phlegmonous lesion. A distinctive suppurrative lesion is usually classified as pyoderma. Deep lesions that cause damage to dermal collagen may cause focal scarring and idiopathic fibrosing dermatitis (see following discussion).

A systemic reaction is likely to occur when the affected skin area is extensive. Shock, with peripheral circulatory failure, may be present in the early stages. Toxemia as a result of absorption of tissue breakdown products, or septicemia as a result of invasion...
via unprotected tissues, may occur in the later stages.

Individual dermatitides are as follows:

- **Interdigital dermatitis** is a low-grade exudative inflammation of the interdigital skin of cattle housed indoors and standing continuously in slurry. This condition has been linked to *Dichelobacter nodosus*.

- **Ovine postdipping necrotic dermatitis** is associated with *P. aeruginosa* and related to dipping in solutions containing no bacteriostatic agent. Necrotic lesions (1 to 3 cm in diameter), with cellulitis down to the underlying muscle, occur only along the backline and may be related to trauma during dipping. It may be accompanied by an outbreak of fatal otitis media with *P. aeruginosa* present in the lesion.

- **Ovine atopic dermatitis**: Only the wool-less parts of the skin are affected by symmetric erythema, alopecia, lichenification, and excoriation. Only occasional sheep in the flock are affected, and these are affected each summer, with remission during the winter months.

- **Caprine idiopathic dermatitis**: Alopecic, exudative dermatitis of all ages and both sexes of pygmy goats is characterized by hair loss and scaling and crusting around the eyes, lips and chin, ears, poll, perineum, and ventral abdomen. Histologically the lesions have a psoriasis-like form.

- **Chronic equine eosinophilic dermatitis** is characterized by marked accumulations of eosinophils in the epidermis or loss of hair, and with no apparent itching or pain. The lesions occur symmetrically on most parts of the body, persist for long periods, and increase in size up to 5 cm to form annular or crescent-shaped wheels. Spontaneous disappearance of the lesions after about 3 months is usual. Symptomatic treatment may be effective but is not usually necessary.

- **Equine nodular necrobiotic dermatitis (eosinophilic granuloma)**: Firm, small (up to 1 cm in diameter) nodules, usually a number of them, occur on the sides of the trunk and neck. A hypersensitivity reaction to insect bites has been proposed as the underlying cause. The lesions consist largely of an accumulation of eosinophils.

- **Molluscum contagiosum** is a chronic progressive dermatitis characterized by raised, hairless lesions 0.5 to 2 cm in diameter, covered by soft keratin, that bleed profusely when the horse is groomed. The lesions are on the face, shoulders, trunk, lateral aspects of limbs, fetlocks, and pasterns. Histologic examination identifies the disease because of the presence of characteristic inclusions in cells. These are thought to be poxvirus virions, but the virus cannot be cultivated from the lesions. There is no specific treatment

- **Systemic lupus erythematosus (SLE)** is an extensive dermatitis, manifested as a scaly, crusty dermatitis of the face, neck, and trunk, with loss of hair over the lesions, edema of the limbs, and mild to moderate lymph node enlargement. Multiple ulcers 11 cm in diameter are present on the oral mucosa, especially the mucocutaneous junctions of the lips and nares, and on the tongue. There is a severe systemic reaction, including a marked loss of body weight, a temperature up to 39.5°C (103.1°F), heart rate of 80/min, respiratory rate up to 60/min, painful swollen joints containing sterile serous fluid, stiff gait, reluctance to move, and persistent lateral recumbency. SLE is an immunemediated disease with a characteristic histopathology including a necrotizing lymphocytic dermatitis and focal accumulations of lymphocytes in the liver, membranous glomerulonephritis, and synovioyte hyperplasia. An antinuclear antibody test is diagnostic. No treatment is effective, and the disease runs a chronic progressive course marked by remissions and exacerbations.

- **Discoid lupus erythematosus** is an uncommon, benign variant of the major disease but similar to those in the major disease but with no involvement of other tissues.

- **Erythema multiforme** is a self-limiting skin disease of horses and cattle characterized by macular, papular, urticarial, or bullous skin lesions but without any abnormality of the epidermis or loss of hair, and with no apparent itching or pain. The lesions occur symmetrically on most parts of the body, persist for long periods, and increase in size up to 5 cm to form annular or crescent-shaped wheels. Spontaneous disappearance of the lesions after about 3 months is usual. Symptomatic treatment may be effective but is not usually necessary.

- **Equine aural plaque**: Multiple white plaques, resembling papilloma and about 1 cm in diameter, develop on the inner surface of the ear pinna of horses. This condition has been associated with the papillomavirus that is thought to be transmitted by biting insects.

- **Equine tropical lichen** is an intensely irritating, papular eruption in the skin on the side of the neck, under the mane, on the shoulders, and at the tailhead, occurring in summer and recurring annually. The disease closely resembles the cutaneous sensitivity to *Culicoides* spp., but responses dramatically to treatment with ivermectin. Microfilariae, thought to be *Onchocerca* spp., can be found in histologic sections.

- **Linear hyperkeratosis** is most common in horses, especially Quarter horses. One case has been recorded in cattle. Lesions appear spontaneously in horses 1 to 5 years old and persist, usually for life. They appear first as isolated scaly lumps, which then coalesce to form a ridge, usually vertical, 3 to 4 cm wide and up to 70 cm long, of hyperkeratotic, hairless skin. There may be one or more lesions, commonly on the sides of the neck and chest. Symptomatic treatment appears to have no effect on the lesions.

- **Idiopathic fibrosing dermatitis**: The end stage of several severe dermatoses, this causes damage to dermal collagen. Manifested by multiple fibrous plaques in the skin caused by sclerosis of the skin or subcutis, it resembles human morphea and the skin granulomas of animals.

- **Porcine dermatitis–nephropathy syndrome**, an idiopathic low morbidity but highly fatal disease of feeder pigs, is characterized by papular vascular dermatopathy, systemic necrotizing vasculitis, and exudative and proliferative glomerulonephritis. Skin lesions are full-depth necrosis appearing as multiple flat red–blue papules up to 2 cm in diameter (which may coalesce to form large plaques) on any part of the body. Some pigs die of glomerulonephritis without skin lesions having been apparent. Many cases that show only skin lesions recover spontaneously in several weeks. The disease may disappear if the commercial grain ration used is ground more coarsely.

- **Porcine necrotic ear syndrome** is an extensive necrosis of the edges of the ears. The cause is unknown, but the possibility that a combination of *S. hyicus* infection and trauma by biting by pen mates is the cause seems high.

- **Porcine idiopathic chronic, recurrent dermatitis** has been recorded in sows in specific farrowing houses. Boars and piglets were not affected, and lesions disappeared as soon as the sows left the houses. Annular macules 11 cm in diameter and patches of erythema 11 cm in diameter occur only on white skin. There are no systemic signs.

- **Equine staphylococcal pyoderma** is a serious disease because the lesions are intractable to treatment and are so painful to touch that the horse is hard to handle, and the presence of the lesions under the harness, where they
commonly are, prevents the horse from working kindly. Harness horses are at a particular disadvantage. Individual lesions are raised nodules, 3 to 5 mm in diameter, covered by a small, easily removed scab. When these lift, they take a tuft of hair with them, and a small crater is left. A little pus exudes, and only a red serous fluid can be expressed. Individual lesions last a long time, at least several weeks, and fresh crops occur, causing the disease to spread slowly on the animal.

**Pemphigus**

Pemphigus is an autoimmune disease of the skin occurring in mature horses, usually 5 years of age or older, as well as in foals. Vesicles and pustules are usually very difficult to find because they progress rapidly to crusts, exfoliation, alopecia, and scaling. There are a number of manifestations, of which pemphigus foliaceus is the most common. Pemphigus vulgaris and bullous pemphigoid, in contrast, are rare. Pemphigus is a chronic autoimmune disease often accompanied by severe weight loss.

**Pemphigus foliaceus** is not only the predominant form of pemphigus but also the most common autoimmune disease of the horse. The classic, but rarely seen, primary lesion is a vesicle or pustule. Usually, the earliest lesions visible are crusty papules best seen in lightly or non-haired skin adjacent to mucuscaneous junctions—the nostrils, eyelids, or lips. Lesions rapidly coalesce to form multifocal or diffuse areas of crusting. Pemphigus foliaceus occurs as a generalized scabby, weeping dermatitis, but it may be localized as circumscribed, circular lesions in the mouth and vulva and on the skin at mucocutaneous junctions. The lesions are subepidermal bullae, from which the top crater is left. A little pus exudes, and only a red serous fluid can be expressed. Individual lesions last a long time, at least several weeks, and fresh crops occur, causing the disease to spread slowly on the animal.

**CLINICAL PATHOLOGY**

Examination of skin scrapings or swabs for parasitic, bacterial, or other agents is essential. Culture and sensitivity tests for bacteria are advisable to enable the best treatment to be selected. Skin biopsy may be of value in confirming the diagnosis and determining the causal agent. In allergic or parasitic states there is usually an accumulation of eosinophils in the inflamed area. In mycotic dermatitis organisms are usually detectable in the deep skin layers, although they may not be cultivable from superficial specimens.

**DIAGNOSIS**

The clinical features of dermatitis are apparent. The characteristic features of the etiologic types of dermatitis are described under each specific disease. **Diagnostic confirmation** is by histopathological demonstration in a biopsy specimen.

**DIFFERENTIAL DIAGNOSIS**

Hyperhidrosis and anhidrosis are dysfunctions of sweating and have no cutaneous lesion. Cutaneous neoplasm is differentiable on histopathological examination. Epitheliogenesis imperfecta is a congenital absence of all layers of skin. Vascular nevus is a congenital lesion commonly referred to as a “birthmark.”

**TREATMENT**

Primary treatment must be to remove the noxious physical or chemical agent from the environment or to supplement the diet to repair a nutritional deficiency. The choice of a suitable treatment for infectious skin disease will depend on the accurate identification of the etiologic agent.

Supportive treatment includes both local and systemic therapy. Local applications may need to be astringent, either as powders or lotions in the weeping stage or as greasy salves in the scabby stage. The inclusion of corticosteroids or antihistamine preparation is recommended in allergic states, and it is desirable to prescribe sedative or anesthetic agents when pain or pruritus is severe.

If shock is present, parenteral fluids should be administered. If the lesions are extensive or secondary bacterial invasion is likely to occur, parenterally administered antibiotics or antifungal agents may be preferred to topical applications. To facilitate skin repair, a high-protein diet or the administration of protein hydrolysates or amino acid combinations may find a place in the treatment of valuable animals. Nonspecific remedies such as gold-containing remedies (e.g., aurothioglucose) are commonly used in autoimmune diseases such as pemphigus.

The use of vaccines as prophylaxis in viral and bacterial dermatitides must not be neglected. Autogenous vaccines may be most satisfactory in bacterial infections. An autogenous vaccine is particularly recommended in the treatment of staphylococcal dermatitis in horses and bovine udder impetigo, in which long and repeated courses of treatment with penicillin produce only temporary remission. An autogenous vaccine produces a cure in many cases.

**REFERENCES**

**PHOTOSENSITIZATION**

**SYNOPSIS**

**Etiology** Caused by the accumulation of photosensitizing substances (PSs) in the skin, resulting in the local irritation of unprotected, unpigmented skin after exposure to sunlight. Four types of photosensitization are differentiated based on the underlying etiology.

Type I, or primary, caused by intake of primary PS.

Type II, as a result of inherited defects of porphyrin metabolism.

Type III, or hepatogenous, as a result of liver damage and ensuing faulty excretion of phylloerythrin.

Type IV, or idiopathic, as a result of undetermined etiology.

**Epidemiology** Exposure to PSs and sunlight of specific wavelength. Similar incidence of sporadic cases and outbreaks. Always life-threatening condition unless exposure to sunlight can be avoided.

**Clinical signs** Primary cases have cutaneous signs only (erythema, edema, necrosis, gangrene of light-colored skin or mucosae exposed to sunlight). Secondary cases have also signs of hepatic dysfunction (jaundice, prostration, short course, death) or porphyrin metabolism.

**Clinical pathology** Nil for evidence of photosensitivity. In secondary cases there is evidence of the primary disease.

**Necropsy lesions** Only skin lesions in primary cases. Secondary cases show liver lesions or evidence of porphyrin accumulation.

**Differential diagnosis** Clinical evidence of restriction of damage to white, wool-less skin on body dorsum and lateral aspects of limbs, teats, cornes, and tongue and lips.

**Treatment** Primary: remove from exposure to sunlight and PS. Supportive: treat for infection, shock, toxemia.

**ETIOLOGY AND EPIDEMIOLOGY**

Photosensitization is caused by exposure of tissue containing certain photoactive
substances to light of specific wavelength. Substances with the potential to accumulate in skin and get activated by solar irradiation are termed photosensitizing substances (PSs). Skin containing an excess of PSs that is exposed to sunlight while unprotected by hair, wool, or pigmentation is most affected. PSs release unstable high-energy molecules when exposed to a wavelength of light above 320 nm that reacts with substrate molecules in the skin. The result is the formation of free radicals causing cell damage in outer cells and becoming clinically apparent as inflammation, edema, ulceration, and even necrosis of the skin.

Photosensitization differs from sunburn in that it requires the presence of a photosensitizing agent, it is triggered by exposure to a wavelength of light between 320 and 400 nm (in contrast to sunburn, which in most cases is the result of exposure to light with lower wavelength), its onset is rapid (in contrast to sunburn, which in most cases occurs in a delayed manner after exposure), and skin lesions are considerably more severe than with sunburn.

Based on the origin of the photosensitizing agent, photosensitization has been classified into four classes, as follows:

- **Type I**, primary photosensitization caused by PSs of exogenous origin (no underlying primary pathology of the organism)
- **Type II**, photosensitization caused by aberrant pigment metabolism
- **Type III**, hepatogenous photosensitization caused by disturbed liver function
- **Type IV**, idiopathic photosensitization that is of undetermined etiology

Another form of photosensitization that is of little importance in livestock is the photoallergic photosensitization related to an immunologic response involving T-cell-mediated delayed hypersensitivity.

**Type I, Primary Photosensitization**
Exogenous PSs can enter the organism through oral ingestion (e.g., PSs contained in feed), parenteral administration (e.g., certain drugs), or direct absorption through skin. In livestock oral ingestion is the most common route of exposure, with PSs being either contained in the diet or, less commonly, an orally administered drug. Photosensitization as a result of the ingestion of exogenous photodynamic agents usually occurs when the plant is in the lush green stage and is growing rapidly. Livestock are affected within 4 to 5 days of going to pasture, and new cases cease soon after the animals are removed. In most cases the plant responsible must be eaten in large amounts and will therefore usually be found to be a dominant inhabitant of the pasture. All species of animals are affected by photodynamic agents, although susceptibility may vary between species and between animals of the same species. PSs that occur naturally in plants include the following:

- Dianthrone derivatives—hypericin in *Hypericum perforatum* (St. John's wort) and other *Hypericum* spp. and fagopyrin in seeds and dried plants of *Fagopyrum esculentum* (buckwheat)
- Furocoumarins in *Cymopterus* spp. (wild carrot), *Ammi majus*, and *Thamnosma texana*
- Perloline from perennial ryegrass (*Lolium perenne*)
- Cocoa shells in feedlot rations causing photosensitization in feedlot calves
- Gluten metabolites in dairy cattle concentrates being fed to horses
- *Erodium moschatum*, an exotic weed in South Africa, causing photosensitization in sheep
- Unidentified photodynamic agents in *Medicago denticulata* (burr trefoil) and the aphids that infest it, and in *Brassica* spp., *Erodium* spp., and *Trifolium* spp.

Drug-related photosensitization has been reported after oral treatment with phenothiazine, an antipsaritic drug, and anecdotally after treatment of cows with corticosteroids to induce parturition (photosensitive dermatitis of the teats, escutcheon, and udder).

**Type II, Photosensitization as a Result of Aberrant Pigment Metabolism**
The PSs associated with type II photosensitization are porphyrins that may accumulate in an organism with disturbed heme synthesis. The only known examples of domestic animals are the two rare inherited conditions of congenital porphyria erythropoietica (pink tooth) and congenital protoporphyrinia erythropoietica described in Limousin cattle.

**Type III, Hepatogenous Photosensitization**
Hepatogenous photosensitization is the most common form of the disorder in livestock. The PS is invariably *phylloerythrin*, a normal end product of chlorophyll metabolism excreted in the bile. When biliary secretion is obstructed by hepatitis or biliary duct obstruction, phylloerythrin accumulates in the body and may reach levels in the skin that make it sensitive to light. Although hepatogenous photosensitization is more common in animals grazing green pasture, it can occur in animals fed entirely on hay or other stored feeds and in animals exposed to hepatotoxic chemicals (e.g., carbon tetrachloride). There appears to be sufficient chlorophyll, or breakdown products of it, in stored feed to produce critical tissue levels of phylloerythrin in affected animals. The following list includes those substances or plants that are common causes of hepatogenous photosensitization. The individual plants are discussed in more detail in the section on poisonous plants.

**Plants Containing Hepatotoxins**
- *Pithomyces chartarum* fungus on perennial ryegrass, causing facial eczema of sheep
- *Periconia* spp. fungus on Bermuda grass
- Cyanobacteria associated with blue-green algae (water bloom) on drinking water in ponds, dams, and dugouts—Microcystis flosaquae
- Lupins—*Lupinus angustifolius* plus the accompanying fungus, *Phomopsis leptostromiformis*
- Signal grass (*Brachiaria decumbens* and *Brachiaria brizantha*), a common component of established pastures in Brazil
- Alligator weed (*Alternanthera philoxeroides*), a South American aquatic plant causing photosensitization in dairy cattle in Australia and New Zealand
- Weeds, including lantana (*Lantana camara*), lippia (*Lippia rehmanni*), sacahuiste (*Nolina texana*), coal oil bush (*Tetradymina spp.*), alecrim (*Holocalyx glaziovii*), ngaio (*Myoporum laetum*), *Crotalaria retusa*, ragwort (*Senecio jacobaea*), *Sphenosciadium* spp.

**Plants Containing Steroidal Saponins**
The following plants containing steroidal saponins cause crystal-related cholangiohepatopathies:

- *Agave lechequilla*, *Narthecium ossifragum*, *Panicum* spp. (panic and millet grasses), and *Tribulus terrestris* (caltrop, geeldoikkop), plants that are grazed particularly by sheep
- *Narthecium ossifragum* (bog asphodel)—Sheep (lams) grazing on pastures containing *N. ossifragum* on the west coast of Norway and in Scotland, northern England, Ireland, and the Faroe Islands have been affected by alveld, a hepatogenous photosensitivity disease. The disease is known as alveld (literally, “elf fire”) in Norway; plochtteach, saut, or ylowesses in the British Isles; and ormajuka (“worm disease”) in the Faroe Islands. Pastures containing *N. ossifragum* in these countries are commonly used for grazing sheep. Photosensitization of sheep grazing this plant usually occurs in 2- to 6-month-old lambs and is rarely seen in adult sheep. It produces similar clinical signs to those resulting from facial eczema, a disease most commonly seen in New Zealand and associated with the fungal toxin sporidesmin.

**Congenitally Defective Hepatic Function**
Inherited congenital photosensitivity in Corriedale and Southdown lambs is an inherited defect in the excretion of bile pigment.
Diseases of the Epidermis and Dermis

Type IV. Photosensitization of Uncertain Etiology

In the following diseases it has not been possible to ascertain whether the photosensitization is primary or as a result of hepatic insufficiency:

- Feeding on rape or canola (Brassica rapa), kale, lucerne or alfalfa (Medicago sativa), burr medic or burr trefoil (Medicago denticulata), Medicago minima, Trifolium hybridum (alisk or Swedish clover), and Erodium cicutarium and Erodium moschatum (lamb’s tongue, plantain)
- Cattle feeding on water-damaged or moldy alfafa hay or alfalfa silage; extensive outbreaks usually with no signs suggestive of hepatic disease
- Cattle, sheep, and horses grazing lush pasture; many clinical cases occur sporadically
- Corticosteroids used systemically to terminate parturition in cows
- Phenathridium used in the treatment of trypanosomiasis

PATHOGENESIS

Penetration of light rays to sensitized tissues causes local cell death and tissue edema. Irritation is intense because of the edema of the lower skin level, and loss of skin by necrosis or gangrene and sloughing is common in the terminal stages. Nervous signs may occur and are caused either by the photodynamic agent, as in buckwheat poisoning, or by liver dysfunction.

Hepatogenous photosensitization involves production of a toxin, by a higher plant, fungus, or cyanobacterium (algae), that causes liver damage or dysfunction, resulting in the retention of the photosensitizing agent phylloerythrin.

CLINICAL FINDINGS

General Signs

Skin lesions are limited to lightly or unpigmented skin directly exposed to light; pigmented parts of the integument remain unaffected. Early signs include erythema and swelling of the muzzle, nasal and ocular discharge, and photophobia. Local edema is often severe and may cause drooping of the ears; closure of the eyelids and nostrils, causing dyspnea; and dysphagia as a result of swelling of the lips. As the disease progresses, fissuring followed by sloughing of the thick skin is observed. Keratitis may be present and become severe enough to cause blindness. Behavioral changes are a result of intense irritation and include restlessness and scratching and rubbing of affected skin parts. When the teats are affected, the cow may kick at them and walk into ponds to immerse the teats in water, sometimes rocking backward and forward as if to cool the affected parts. In nursing ewes there may be resentment toward the lambs sucking, and heavy lamb mortalities as a result of starvation may result.

Skin Lesions

Skin lesions are initially erythema, followed by edema and subsequent weeping with matting and then shedding of clumps of hair, and finally gangrene. The lesions have a characteristic distribution, restricted to the unpigmented areas of the skin and to those parts that are exposed to solar rays. They are most pronounced on the dorsum of the body, diminishing in degree down the sides, and are absent from the ventral surface. The demarcation between lesions and normal skin is very clear-cut, particularly in animals with broken-colored coats.

Predilection sites for lesions are the ears; conjunctiva, causing opacity of the lateral aspect of the cornea; eyelids; muzzle; face; lateral aspects of the teats; and, to a lesser extent, the vulva and perineum. In solid black cattle dermatitis will be seen at the lips of the vulva, on the edges of the eyelids, and on the cornea. Linear erosions often occur on the tip and sides of the tongue in animals with unpigmented oral mucosa. In severe cases the exudation and matting of the hair and local edema cause closure of the eyelids and nostrils. In the late stages necrosis or dry gangrene of affected areas leads to sloughing of large areas of skin.

Systemic Signs

Systemic signs include shock in the early stages, as a result of extensive tissue damage. There is an increase in the pulse rate, with ataxia and weakness. Subsequently a considerable elevation of temperature (41° to 42°C, 106° to 107°F) may occur.

Nervous Signs

Nervous signs, including ataxia, posterior paralysis and blindness, and depression or excitement, are often observed. A peculiar sensitivity to water is sometimes seen in sheep with facial eczema; when driven through water, they may lie down in it and have a convulsion.

CLINICAL PATHOLOGY

In most cases a presumptive diagnosis can be made based on clinical presentation in combination with the history of the patient (recently pastured, access to certain plants, etc.). There are no specific diagnostic tests to confirm photosensitization.

Hepatogenous photosensitization can be diagnosed by analysis of plasma phylloerythrin concentration using a spectroscopic method. Plasma or serum fluorescence can be used to measure the elevation of phylloerythrin above normal levels before hepatogenous photosensitization. The levels of phylloerythrin in plasma of lambs grazing N. ossifragum are increased from a normal of less than 0.05 µg/mL to more than 0.3 µg/mL when clinical signs of photosensitization are observed. Levels in skin are also increased. In lambs in which facial eczema was experimentally induced by dosing with the mycotoxin sporidesmin, the plasma concentrations of phylloerythrin were increased from a normal of less than 0.1 µmol/L to 0.3 µmol/L when clinical signs were evident. The concentration of phylloerythrin in the skin began increasing 2 to 3 days later than that in the blood.

Determining the presence of liver damage or disturbed liver function is indicated. Icterus is highly suggestive of hepatogenous hypersensitization but should be confirmed by measuring the serum activity of specific liver enzymes and the serum bilirubin concentration.

Necropsy Findings

In primary photosensitization, lesions are restricted to white-haired or pale-skinned areas of skin or mucosa that have been exposed to sunlight, and they vary from necrosis to gangrene. Lesions characteristic of hepatic injury or metabolic defects of porphyrin metabolism are described elsewhere.

Diffuse hepatocellular hydropic degeneration and hyperplasia of the smooth endoplasmic reticulum associated with marked multifocal cholangitis in the portal triads with bile duct proliferation are characteristic of the hepatic lesions of sheep grazing Brachiaria decumbens. Foam cells are present in the liver and mesenteric and hepatic lymph nodes of cattle grazing Brachiaria spp. Hepatocellular degeneration is the primary event in alveld photosensitization in sheep. High concentrations of conjugated episapogenins are present in both the liver and bile in alveld-affected lambs.

Differential Diagnosis

The diagnosis of photosensitivity depends almost entirely on the distribution of the lesions. It can be readily confused with other dermatitides if this restriction to unpigmented and hairless parts is not kept in mind.

Mycotic dermatitis is often mistaken for photosensitization because of its tendency to commence along the back line and over the rump, but it occurs on colored and white parts alike.

Frequent wetting, as in periods of heavy rainfall, along the back, in horses or cattle with a dense hair coat.

Bighead of rams associated with Clostridium novyi infection may also be confused with photosensitization, but the local swelling is an acute inflammatory edema, and many clostridia are present in the lesion.

Keratitis sometimes seen in photosensitization can be confused with those of pinkeye, but that disease is not accompanied by extensive dermatitis.

Continued
Sunburn is a very rare differential that has been reported in white swine, closely shorn sheep, and white-faced horses only.

Treatment

Primary treatment includes immediate removal from direct sunlight, prevention of ingestion of further toxic material, and the administration of laxatives to eliminate toxic materials already eaten. In areas where the disease is enzootic the use of dark-colored doors, feed troughs, or tethers in confined housing; rubbing against harness in working animals

• Poisoning by thallium, selenium, arsenic, mercury, or the tree Leucaena leucocephala

• Idiopathic hair loss from the tail-switch of well-fed beef bulls

• Sterile eosinophilic folliculitis of cattle

• Wool slip

• In many primary skin diseases (e.g., parakeratosis, hyperkeratosis, dermatitis, cutaneous neoplasia, sarcoid, pythiosis), hair loss at the site of local lesions

Pathogenesis

In inherited hair defects the underlying cause can be disturbed hair follicle formation resulting in a reduced hair follicle quantity or disturbed functionality of hair follicles that are present in adequate numbers. Noncicatricial alopecia is caused by reversible trauma to previously functional hair follicles by inflammation or mechanical trauma, which results in disturbed or interrupted synthesis in the hair bulb and ensuing shedding or fracture of hairs. Cicatricial alopecia is characterized by an irreversible destruction of hair follicles most commonly caused by physical, chemical, or thermal injury or severe inflammation.

Chemical depletion produced by cytotoxic agents, such as cyclophosphamide, occurs as a result of induced cytoplasmic degeneration in some of the germinative cells of the bulb of the wool follicle. The alteration in cell function is temporary, so that regrowth of the fiber should follow.

The pathogenesis of alopecia areata, primarily occurring in horses but also in cattle, has been associated with damage to growing hair mediated by T lymphocytes presumably specific for antigens of the hair matrix (autoimmune disease). A genetic predisposition for alopecia areata has been discussed for humans.

Clinical Findings

When alopecia is a result of breakage of the fiber, the stumps of old fibers or developing new ones may be seen. When fibers fail to grow, the skin is shiny and in most cases is thinner than normal. In cases of congenital follicular aplasia, the ordinary covering hairs are absent, but the coarser tactile hairs around the eyes, lips, and extremities are often present. Absence of the hair coat makes the animal more susceptible to the effects of sudden changes of environmental temperature. There may be manifestations of a primary disease and evidence of scratching or rubbing.

Alopecia areata in horses primarily affects the mane, head, and tail, whereas in cattle extensive alopecia affecting large parts of the body has been reported. Cases reported in the literature are primarily from animals showing first signs at adult age. In cattle a predisposition of black-haired breeds (Black
Angus, Aberdeen Angus, Eringer) has been proposed. Congenital hypotrichosis results in alopecia that is apparent at birth or develops within the neonatal period.

**CLINICAL PATHOLOGY**

If the cause of the alopecia is not apparent after the examination of skin scrapings or swabs, a skin biopsy will reveal the status of the follicular epithelium. Alopecia areata is characterized by bulbar and peribulbar lymphocyte infiltration, primary targeting anagen hair follicles. In early stages several biopsies may be required to identify this pattern of infiltration. More advanced stages show dysplastic follicles with mild to moderate concentric fibrosis surrounding rudiments of hair bulbs.

### Differential Diagnosis

Diagnostic confirmation of alopecia is by visual recognition, the diagnostic problem being to determine the primary cause of the hair or fiber loss.

**TREATMENT**

Primary treatment consists of removing the causes of trauma or other damage to fibers. In cases of faulty follicle or fiber development treatment is not usually attempted.

**FURTHER READING**

**REFERENCES**

**ACHROMOTRICHIA**

Achromotrichia is a deficient pigmentation in hair or wool fiber, which may manifest as follows:

- General loss of density of pigmentation in all coat colors (e.g., Hereford cattle shade off from their normal deep red to a washed out orange)
- Albinism and lethal white foal syndrome: Albinism refers to a congenital lack of melanin pigment in skin, hair, and other normally pigmented tissues. Albinism can occur as partial or complete albinism, the latter being inherited as autosomal-dominant trait that is only viable in the heterozygous state. The homozygous state results in a nonviable embryo that is resorbed in early gestation. A different form of lethal white foal syndrome results in homozygous expression of the associated trait and affects a subset of American Paint horses with the so-called frame overo color pattern.

**LEUKODERMA AND LEUKOTRICHIA**

Several skin diseases of the horse are characterized by an acquired loss of melanin pigment in the epidermis or hair. Melanocytes in the epidermis and those in the hair bulbs are frequently affected independently. Leukotrichia occurs when the melanocytes in the hair bulbs lose their normal amount of melanin pigment. When the melanocytes in the epidermis are affected and the skin loses normal pigmentation, the abnormality is leukoderma. Whereas leukotrichia can be observed as a single entity, leukoderma is most commonly associated with leukotrichia.

**ETIOLOGY**

The etiology and pathogenesis of leukoderma are unknown, but trauma, inflammation, autoimmune reactions against melanocytes, local injections with epinephrine-containing local anesthetics, and defects of the autonomous nervous system have been discussed. Specific forms of leukoderma have been linked to hereditary gene defects (see following discussion).

**PATHOPHYSIOLOGY**

The unknown underlying cause appears to result in acquired loss of functional melanocytes.

**CLINICAL FINDINGS**

The forms of leukotrichia/leukoderma have been reported in horses:

- *Reticulated leukotrichia*: Alopecia and ensuing leukotrichia in a characteristic cross-hatched or reticulated pattern. Yearlings and occasionally older animals are affected, and Quarter horses appear to be predisposed.
- *Spotted leukotrichia*: Multiple, sharply demarcated area of leukotrichia of 1 to 3 cm in diameter.
- *Juvenile Arabian leukoderma*: Most common form of leukoderma in horses, reported in young Arabian and occasionally in Quarter horses. One- to 2-year-old animals develop leukoderma on eyelids, periorcular skin, muzzle, nares, genitalia, anus perineum, and inguinal region.
- *Hyperesthetic leukotrichia*: Condition of unknown etiology that is characterized by the development of single or multiple very painful crusts on the dorsal midline from withers to tail. Crusts disappear and pain resolves after 2 to 3 months, while leukotrichia persists.

**VITILIGO**

Vitiligo is a presumably acquired autoimmune disorder characterized by patchy depigmentation of the skin described in horses, cattle, and other species.

**ETIOLOGY**

Although the etiology of vitiligo is still unknown, evidence corroborating the hypothesis that vitiligo is an acquired autoimmune disease associated with the production of antimalanocyte antibodies has accumulated over the last decades. Other etiologies discussed in the literature are an increased susceptibility of melanocytes to certain melatonin precursor molecules or local nerve injuries. A genetic etiology is suspected in Arabian horses and Holstein–Friesian cattle.

**PATHOPHYSIOLOGY**

The underlying cause results in a complete, although sometimes reversible, loss of functional melanocytes in a small area of the dermis.

**CLINICAL FINDINGS**

Vitiligo has been reported in different breeds, without apparent gender predisposition. Although the condition can develop at any age, it most commonly is observed in young animals. Typical presentation is a patchy depigmentation of the skin of the muzzle, eyelids, and occasionally anus and other body regions. The degree of depigmentation can vary over time, and the condition may even completely resolve, making the...
interpretation of anecdotal treatment successes difficult. The defect is esthetic only.

**CLINICAL PATHOLOGY**

Histopathological examination reveals a complete absence of melanocytes from affected areas. Increased numbers of Langerhans cells and epidermal vacuolization have been reported in some cases.¹

**TREATMENT**

No specific treatment with confirmed efficacy is currently available. Anecdotal reports of improvement after supplementation of vitamins and minerals (vitamin A and copper) are available.² Because of the possible genetic predisposition, the use of affected animals for breeding has been discouraged.

---

**SEBORRHEA**

**ETIOLOGY**

The etiology of seborrhea is still not understood. Historically seborrhea was considered to be the result of excessive secretion of sebum onto the skin surface. More recently seborrhea was classified as disease of abnormal cornification and keratinization of the skin rather than of excessive sebum production because there is little evidence for abnormal function of the sebaceous glands. In large animals it is always secondary to dermatitis or other skin irritations that result in excessive crusting, scaling, or oiliness, such as the following:

- Exudative epidermitis of pigs associated with *S. hyicus*
- Greasy heel of horses, including infection with *S. hyicus*
- Greasy heel of cattle
- Flexural seborrhea of cattle
- Besnoitiosis of cattle associated with *Besnoitia besnoiti*

**CLINICAL FINDINGS**

In primary seborrhea there are no lesions, only excessive greasiness of the skin. The sebum may be spread over the body surface like a film of oil or be dried into crusts, which can be removed easily. Sebaceous glands may be hypertrophied.

**Flexural Seborrhea**

Flexural seborrhea is most common in young periparturient dairy cows. Severe inflammation and a profuse outpouring of sebum appear in the groin between the udder and the medial surface of the thigh or in the median fissure between the two halves of the udder. Extensive skin necrosis follows, causing a pronounced odor of decay, which may be the first sign observed by the owner (see also under “Udder Cleft Dermatitis”). Irritation may cause lameness, and the cow may attempt to lick the part. Shedding of the oily, malodorous skin leaves a raw surface beneath; healing follows in 3 to 4 weeks.

**Greasy Heel of Cows**

Cows grazing constantly irrigated, wet pastures or in very muddy conditions in tropical areas may develop local swelling, with deep fissuring of the skin and an outpouring of vile-smelling exudate on the back of the pastern of all four feet but most severely in the hindlimbs. Affected animals are badly lame, and their milk yield declines sharply. Moving the cows to dry land and treating systemically with a broad-spectrum antibiotic effects a rapid recovery.

**Greasy Heel of Horses (Scratches)**

Greasy heel occurs mostly on the hind pasterns of horses that stand continuously in wet, unsanitary stables. Some cases do occur in well-managed stables. It has been suggested that secondary infections associated with either *S. aureus* and *D. congolensis* may be causative factors. Dermatophytosis, choriotic mange, and photosensitization are also possible causative factors.

Lameness and soreness to touch are a result of excoriations called scratches on the back of the pastern that extend down to the coronary band. The skin is thick and greasy; if neglected, the condition spreads around to the front and up the back of the leg. This involvement can be severe enough to interfere with normal movement of the limb.

**CLINICAL PATHOLOGY**

The diagnosis is based on the clinical presentation and on ruling out other skin conditions resulting in abnormal cornification and keratinization. The primary cause of the seborrhea may be diagnosed by a suitable examination for the presence of parasitic or bacterial pathogens. Histopathology may be supportive to rule out other causes.

**DIFFERENTIAL DIAGNOSIS**

The lesion is characteristic, and diagnostic confirmation is by histopathological examination of a biopsy specimen; the principal difficulty is to determine the primary cause. All the types listed may be mistaken for:

- Injury, commonly wire cuts or rope burn
- Flexural seborrhea for injury, usually a result of straddling a gate or wire fence
- Greasy heel of horses for choriotic mange

**TREATMENT**

With secondary seborrhea the primary objective of treatment must be to resolve the underlying cause. Topical and symptomatic treatment of the affected skin is indicated for relief and to assist in control of the disease. Seborrhoeic shampoos and lotions can either be keratolytic or keratoplastic. Keratolytic products may initially worsen the scale production by chemically debriding the stratum corneum but will eventually result in reduced scale formation. Particularly during the initial phase, frequent washing of the affected skin to remove debrided cells is important. Keratoplastic ointments slow the mitotic rate of the epidermis, thereby reducing scale formation. Emollients are useful after washing the skin to rehydrate, lubricate, and soften the skin. In severe cases associated with pyoderma or even skin necrosis, the use of local and systemic broad-spectrum antibiotics may be indicated.

**FOLLICULITIS**

**ETIOLOGY**

Etiology includes inflammation and possibly infection of hair follicles that can be caused by suppurative organisms (often *staphylococci*), secondary to follicular trauma, obstruction of sebaceous gland ducts, or more rarely as result of an autoimmune reaction. Identifiable forms of folliculitis as individual diseases include the following:

- Staphylococcal dermatitis of horses
- Contagious acne of horses
- Benign facial folliculitis of sucking lambs
- Staphylococcal folliculitis of goats
- Bovine sterile eosinophilic folliculitis

**PATHOGENESIS**

Depending on the underlying etiology, inflammatory cells infiltrate the walls and lumen of hair follicles. With more extensive inflammation, neutrophils may also infiltrate perifollicular tissue, resulting in formation of larger abscesses (*furunculosis*). Increased pressure and tissue lysis will result in a rupture of the hair follicle with an ensuing granulomatous dermal reaction.

**CLINICAL FINDINGS**

Folliculitis may present with skin lesions in almost any location of the skin. Early stages present as papules or pustules with hairs emerging through the lesions. Involvement of the hair follicle allows one to differentiate this condition from impetigo, where the hair follicle is not involved.¹ Later focal crusting and alopecia and pruritus may develop. Pustule rupture leads to contamination of the surrounding skin and development of further lesions, such as ulcerations and draining tracts. Severe cases can be associated with pain, pyrexia, and feed-intake depression. Chronic folliculitis can affect skin pigmentation and cause permanent destruction of hair follicles, which results in cicatricial alopecia.

In *bovine sterile eosinophilic folliculitis*, the multiple lesions are crusted, alopecic,
3- to 5-cm-diameter nodules on all parts of the body except the limbs. They are composed largely of eosinophilic cells and are negative on culture.

**Staphylococcal folliculitis in goats** can be generalized, with pustules developing in the periocular and periauricular area, ventral abdomen, medial thighs, and distal limbs. Involvement of the udder skin can occasionally occur.

**Benign folliculitis of suckling lambs** can develop from the first week of life and consists of small pustules and crusts on the lips, nostrils, ventral tail, and perineum. The condition resolves spontaneously over several weeks.

**CLINICAL PATHOLOGY**

Swabs should be taken for bacteriologic and parasitologic examination. Histopathological findings include microabscesses associated with hair follicles, along with abscessation and necrosis of the epidermis, dermis, and subcutaneous tissue. Cellular infiltration with mononuclear cells and granulocytes is another common finding.

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation is by demonstration of infection of hair follicles in a biopsy specimen.

Udder impetigo of cattle; lesions do not involve hair follicles in the first place.

Dermatophytosis

Dermatophilosis

Besnoitiosis of cattle

Viral infections caused by BHV (types 1, 2, and 4), BVD, bovine parapox virus, cowpox, buffalopox, bluetongue virus, vesicular stomatitis, foot-and-mouth disease

Exudative epidermides of pigs (greasy pig disease) as a result of *S. hyicus*, with extensive seborrheic dermatitis

Ulcerative dermatitis of face in adult sheep

Ecthyma (orf)

Facial eczema of sheep; caused by hepatogenous photosensitization

Leg dermatitis down to coronet of sheep

Chronic pectoral and ventral midline abscesses in horses as a result of *Corynebacterium pseudotuberculosis*; not a skin lesion but it resembles furunculosis.

**TREATMENT**

Primary treatment consists of identifying and eliminating possible primary causes. Topical treatment commences with clipping and cleaning the skin by washing followed by a disinfectant rinse, for instance, with chlorhexidine-based products. Affected areas should be treated with antibacterial ointments or lotions. If the lesions are extensive, the parenteral administration of antibiotics is recommended. The course of treatment should last 1 week; in chronic cases this may need to be at least 1 month; a broad-spectrum preparation is recommended.

For *supportive treatment*, infected animals should be isolated and grooming tools and blankets disinfected.

**REFERENCE**

---

**Diseases of the Subcutis**

**SUBCUTANEOUS EDEMA (ANASARCA)**

**ETIOLOGY**

Extensive accumulation of edema fluid in the subcutaneous tissue is part of general edema and is caused by the same diseases, as follows.

**Increased Hydrostatic Pressure**

- Congestive heart failure
- Vascular compression by a mass (e.g., anterior mediastinal lymphosarcoma, large hemotoma)
- Vascular obstruction of blood vessels or lymphatic vessels (e.g., thrombophlebitis or thrombosis)

**Hydropneumonic (Hypooncotic) Edema**

- Reduced albumin production in the liver associated with chronic inflammation or liver insufficiency (e.g., fascioliasis or liver cirrhosis)
- Nephrotic syndrome with protein loss into urine (e.g., renal amyloidosis in cattle)
- Protein-losing enteropathy (e.g., intestinal nematodiasis or paratuberculosis in cattle)

**Increased Blood Vessel Permeability**

- Inflammation (e.g., dourine of horses or equine infectious anemia, bacterial infections by *Clostridium* spp. or *Anthrax*)
- Allergic reaction (e.g., purpura hemorrhagica of horses, insect stings)

**Fetal Anasarca**

- Some pigs with congenital goiter also have myxedema, especially of the neck.
- Sporadic cases resulting from unknown causes are sometimes associated with deformities (e.g., in Awassi sheep).
- Congenital absence of lymph nodes and some lymph channels causes edema to be present at birth.

**DIFFERENTIAL DIAGNOSIS**

Diagnostic confirmation is by clinical detection of serous fluid in a subcutaneous site.

**PATHOGENESIS**

Alteration in the balance between the hydrostatic pressure of intravascular fluids, the blood and lymph, and the osmotic pressure of those fluids or changes in the integrity of the filtering mechanism of the capillary system can result in fluid extravasation into subcutaneous tissues. There is visible swelling, either local or diffuse. The skin is puffy and pits on pressure; there is no pain unless inflammation is also present. In large animals the edema is usually confined to the ventral aspects of the head, neck, and trunk and is seldom seen on the limbs.

**CLINICAL PATHOLOGY**

Anasarca is a clinical diagnosis, but many estimates (e.g., arterial blood pressure, serum and urine protein levels) provide contributory evidence. Normal total protein concentrations in serum or plasma allow one to rule out hypooncotic edema. Differentiation between obstructive and inflammatory edema can be made by cytologic and bacteriologic examination of the fluid.

**TREATMENT**

Primary treatment requires correction of the primary causal abnormality. Supportive treatment will also depend on the underlying cause but can consist of transfusing plasma or whole blood in cases of hypooncotic edema, or antiinflammatory or diuretic therapy in cases of inflammatory or allergic edema.

**ANGIOEDEMA (ANGIONEUROTIC EDEMA)**

**ETIOLOGY**

Transient, localized subcutaneous edema as a result of an allergic reaction and caused by endogenous and exogenous allergens provokes either local or diffuse lesions. Angioedema occurs most frequently in cattle and horses on pasture, especially during the period when the pasture is in flower. This suggests that the allergen is a plant protein. Fish meal may also provoke an attack.
Recurrence in individual animals is common. Angioedema can also occur as adverse reaction to parenteral administration of certain antibiotics, vaccines, blood, plasma, or other IV fluids.

**PATHOGENESIS**
The precise type of hypersensitivity reaction has not yet been determined, but most cases appear to be associated with a type I or type III hypersensitivity reaction. After an initial erythema, local vascular dilatation is followed by leakage of plasma through damaged vessels.

**CLINICAL FINDINGS**
Local lesions most commonly affect the head, with diffuse edema of the muzzle, eyelids, conjunctiva, and cheeks. Occasionally only the conjunctiva is affected, so that the eyelids are puffy, the nictitating membrane is swollen and protruding, and lacrimation is profuse. Affected parts are not painful to touch, but shaking the head and rubbing against objects suggest irritation. Salivation and nasal discharge may be accompanying signs.

Perineal involvement includes vulvar swelling, often asymmetric, and the perianal skin, and sometimes the skin of the udder, is swollen and edematous. When the udder is affected, the teats and base of the udder are edematous and cows may paddle with the hind limbs, suggesting irritation in the teats. Edema of the lower limbs, usually from the knees or hocks down to the coronets, is more common. In horses, and rarely in cattle, angioedema of the eyelids is puffy, the nictitating membrane is swollen and protruding, and lacrimation is profuse. Affected parts are not painful to touch, but shaking the head and rubbing against objects suggest irritation. Salivation and nasal discharge may be accompanying signs.

Systemic signs are absent, except in those rare cases where angioedema is part of a more widespread allergic response, when bloat, diarrhea, and dyspnea may occur, often with sufficient severity to require urgent treatment.

**CLINICAL PATHOLOGY**
The blood eosinophil count is often within the normal range, but may be elevated from a normal level of 4% to 5% up to 12% to 15%.

**DIFFERENTIAL DIAGNOSIS**
Diagnostic confirmation is found with sudden onset and disappearance of edema at the typical sites.

Subcutaneous edema as a result of vascular pressure occurs mostly in dependent parts and is not irritating. In horses, and rarely in cattle, angioedema may be simulated by purpura hemorrhagica, but hemorrhages are usually visible in the mucosae in purpura.

**TREATMENT**
Primary treatment to remove the specific cause is usually impossible, but affected animals should be removed from the suspected source of allergens. Cattle running at pasture should be confined and fed on dry feed for at least a week.

**Supportive treatment** to relieve the vascular lesion is always administered even though spontaneous recovery is the rule. In acute cases with suspected anaphylaxis, epinephrine should be administered parenterally. For subacute cases, corticosteroids or other antiinflammatories are preferred over antihistamines or epinephrine; usually only one injection is required.

### SUBCUTANEOUS EMPHYSEMA

**ETIOLOGY**
Emphysema, free gas in the subcutaneous tissue, occurs when air or gas accumulates in the subcutaneous tissue as a result of the following:
- Air entering through a cutaneous wound made surgically or accidentally, particularly in the axilla or inguinal region
- Extension from pulmonary emphysema
- Air entering tissues through a discontinuity in the respiratory tract lining (e.g., in fracture of nasal bones; trauma to pharyngeal, laryngeal, and tracheal mucosa caused by external or internal trauma, as in lung puncture by a fractured rib; trauma to the trachea during an attempt to pass a nasoendotracheal tube; following a tracheal wash procedure to assist in the diagnosis of respiratory disease where the trachea does not seal quickly to air movement after removal of the trocar)
- Extension from vaginal lacerations in cattle, particularly in cattle with vaginal prolapse and following dystocia, or cattle with puerperal metritis and gas accumulation in the uterus
- Gases migrating from abdominal surgery because the abdominal cavity is usually at a negative pressure relative to atmospheric pressure
- Gas gangrene infection

**PATHOGENESIS**
Air moves very quickly in a dorsal manner through fascial planes, especially when there is local muscular movement. For example, when a lung is punctured, or in cases of severe interstitial pulmonary edema, air escapes under the visceral pleura and passes to the hilus of the lung, and hence to beneath the parietal pleura, between the muscles, and into the subcutis, particularly between the dorsal aspects of the scapula.

**CLINICAL FINDINGS**
Visible subcutaneous swellings are soft, painless, fluctuating, and grossly crepitant to the touch, but there is no external skin lesion. In gas gangrene, discoloration, coldness, and oozing of serum may be evident. Affected areas of skin are moderately painful to touch. Emphysema may be sufficiently severe and widespread to cause stiffness of the gait and interference with feeding and respiration. The source of the subcutaneous emphysema is usually directly ventral to the most severely affected area, which is usually along the back.

**CLINICAL PATHOLOGY**
Clinical pathology is not necessary except in cases of gas gangrene, when a bacteriologic examination of fluid from the swelling should be carried out to identify the organism present.

**DIFFERENTIAL DIAGNOSIS**
Diagnostic confirmation is based on the observation of crepitus and the extreme mobility of the swelling; these distinguish emphysema from other superficial swellings.

Anasarca, dependent and pits on pressure (see previous discussion).

Hematoma, seroma at injury sites, confirmed by needle puncture (see following discussion).

Cellulitis is accompanied by toxemia, confirmed by needle puncture.

**TREATMENT**
Primary treatment is to address the source of the air, but this may be impossible to locate or to close. Supportive treatment is only necessary in the extremely rare case where emphysema is extensive and incapacitating, in which case multiple skin incisions may be necessary. Gas gangrene requires immediate and drastic treatment with antibiotics.

**LYMPHANGITIS**
Lymphangitis is characterized by inflammation and enlargement of the lymph vessels and is usually associated with lymphadenitis.

**ETIOLOGY**
Lymphangitis in most cases is a result of local skin infection with subsequent spread to the lymphatic system. Common causes are as follows.
Cattle
- Bovine farcy caused by *Mycobacterium farcinogenes* and *Mycobacterium senegalense*
- Cutaneous tuberculosis associated with atypical mycobacteria, rarely *Mycobacterium bovis*

Horse
- Epizootic lymphangitis (equine histoplasmosis) as a result of *Histoplasma capsulatum var. farciminosum*
- Ulcerative lymphangitis as a result of *Corynebacterium pseudotuberculosis*
- Glanders (farcy) caused by *Burkholderia mallei*
- Sporotrichosis
- Sporadic lymphangitis
- Strangles in cases where bizarre location sites occur
- In foals, ulcerative lymphangitis associated with *Streptococcus zooepidemicus*

**PATHOGENESIS**
Spread of infection along the lymphatic vessels causes chronic inflammation and thickening of the vessel walls. Abscesses often develop, with discharge to the skin surface through sinuses.

**CLINICAL FINDINGS**
An indolent ulcer usually exists at the original site of infection. The lymph vessels leaving this ulcer are enlarged, thickened, and tortuous and often have secondary ulcers or sinuses along their course. Local edema may result from lymphatic obstruction. In chronic cases much fibrous tissue may be laid down in the subcutis, and chronic thickening of the skin may follow. The medial surface of the hindlimb is the most frequent site, particularly in horses.

**CLINICAL PATHOLOGY**
Bacteriologic examination of discharge for the presence of the specific bacteria or fungi is common practice.

**TREATMENT**
Primary treatment requires vigorous, early surgical excision or specific antibiotic therapy.

Supportive treatment is directed toward removal of fluid and inflammatory exudate and relief of pain.

**PANNICULITIS**
Panniculitis is diffuse inflammation of subcutaneous fat that has been associated with a number of causes, such as trauma, infection, postinjection site inflammation, insect bite, neoplasia, drug eruption, and dietary factors (excessive intake of polyunsaturated fatty acids or vitamin E deficiency). Deep-seated, firm, and painful nodules or plaques that can reach a diameter of 15 cm or more, often in large numbers, anywhere over the body but especially on the neck and sides, most commonly occur in young horses and rarely in cattle. The lesions may fluctuate greatly in size and number, or even disappear spontaneously. In a few cases there is transient fever, reduced feed intake, and weight loss. Lameness may be evident in horses with extensive lesions.

Diagnosis is by histologic examination of a biopsy specimen. At necropsy examination there are no other lesions. The lesions reduce in size and number after the administration of dexamethasone but recur when treatment stops.

**HEMATOMA**
Hematoma refers to extravasation of whole blood into the subcutaneous tissues.

**ETIOLOGY**
Accumulation of blood in the subcutaneous tissues beyond the limit of that normally caused by trauma may be a result of defects in the coagulation mechanism or a result of increased permeability of the vessel wall.

Common causes include the following:
- Traumatic rupture of large blood vessel
- Dicoumarol poisoning from moldy sweet clover hay
- Purpura hemorrhagica in horses
- Bracken poisoning in cattle; other granulocytopenic diseases manifested principally by petechiation, with lesions observed only in mucosae
- Systemic disease associated with disseminated intravascular coagulopathy (DIC)
- Hemangiosarcoma in subcutaneous sites
- Neonatal bovine pancytopenia
- Inherited hemophilia

**PATHOGENESIS**
Leakage of blood from the vascular system can cause local swellings, which interfere with normal bodily functions but are rarely sufficiently extensive to cause signs of anemia.

**CLINICAL FINDINGS**
Subcutaneous swellings resulting from hemorrhage are diffuse and soft, with no visible effect on the skin surface. There may be no evidence of trauma. Specific locations of subcutaneous hemorrhages in horses include the frontal aspect of the chest—as a result of fracture of the first rib in collisions at full gallop, and often fatal through internal hemorrhage—and perivaginal at foaling, causing massive swelling of the perineum and medial aspect of the thigh.

**CLINICAL PATHOLOGY**
Visual examination of a needle aspirate confirms the existence of subcutaneous hemorrhage. Diagnosis of the primary cause is greatly assisted by platelet counts and prothrombin, clotting, and bleeding times.

**TREATMENT**

**Primary Treatment**
Primary treatment targets removal or correction of the cause.

**Supportive Treatment**
The hematoma should not be opened until clotting is completed, except in the case of a massive hemorrhage that is interfering with respiration, defecation, or urination. If blood loss is severe, blood transfusions may be required. Parenteral injection of coagulants can be justified if the hemorrhages are recent and severe.

**DIFFERENTIAL DIAGNOSIS**
Hematomas as a result of coagulopathies are usually associated with hemorrhages into other tissues, both manifestations being a result of defects in clotting or capillary wall continuity. Single hematomas (e.g., from trauma) must be differentiated from abscesses, seromas, and neoplasias.

Diagnostic confirmation is by needle puncture of the swelling, avoiding excessive blood loss (that would decrease pressure on the leaking vessel) and contamination of a possibly sterile fluid pocket.

**NECROSIS AND GANGRENE**
Necrosis is tissue death; gangrene is sloughing of dead tissue. When either change occurs in the skin, it involves the dermis, epidermis, and subcutaneous tissue.

Different types of gangrene are recognized:
- **Dry gangrene** is primarily caused by arterial occlusion resulting in tissue ischemia. Affected tissue appears dry and shrunken, with dark discoloration and a clear demarcation line from healthy tissue. There is no bacterial infection or putrefaction because bacteria fail to survive in the desiccated tissue.
- **Wet gangrene** is most common after sudden blockage of venous blood flow resulting in ischemia while the affected tissue is saturated with stagnant blood. Tissue trauma (e.g., from mechanical trauma or burns) and ischemia result in release of tissue water and give the affected area a moist and swollen appearance. Because the moist and protein-rich tissue facilitates bacterial growth, infection with saprogenic microorganisms is common. This infection results in the putrid and rotten aspect and odor of the tissue and may cause septicemia.
- **Gas gangrene** is caused by *C. perfringens* (see also “Malignant Edema”).
ETIOLOGY
Severe damage to the skin in the following categories causes gangrene:

- Severe or continued trauma (e.g., pressure sores, saddle and harness galls, carpal or tarsal necrosis in recumbent animals)
- Strong caustic chemicals (e.g., creosote)
- Severe cold or heat, with bushfires and stable fires being the worst offenders. Frostbite is an unusual occurrence in animals unless the patient has a circulatory deficit (e.g., in the neonate, in severe shock or toxemia).
- Beta-irradiation
- Infections, especially:
  - Erysipelas and salmonellosis in pigs
  - Clostridial infections in cattle, affecting subcutis and muscle
  - Staphylococcal mastitis in cattle; Pasteurella multocida in sheep
  - Bovine ulcerative mammillitis of the udder and teats
- Local vascular obstruction—obstruction by thrombi or arterial spasm causes skin gangrene but includes deeper structures, also from poisoning by:
  - Claviceps purpurea
  - Festuca arundinacea (probably as a result of an accompanying fungus)
  - Aspergillus terreus
  - Mushrooms
- Intradermal injection of local anesthetics containing epinephrine have been associated with dry gangrene of injected skin in cattle.

Similar cutaneous and deeper-structure involvement occurs in systemic infections in which bacterial emboli block local vessels (e.g., in salmonellosis in calves, and after tail vaccination of calves with Mycoplasma mycoides).

Other Causes
- Final stages of photosensitive dermatitis and flexural seborrhea
- Screw-worm infestation

PATHOGENESIS
The basic cause of gangrene is interference with local blood supply by external pressure; by severe swelling of the skin, as in photosensitization; or by arteriosclerotic spasm or damage to vessels by bacterial toxins.

CLINICAL FINDINGS
With dry gangrene the lesion is dry from the beginning, and the area is cold and sunken, with red–brown discoloration and without offensive odor, resembling mummified tissue. Bacterial infection is commonly not present. Sloughing of dry tissue may take a long time, and the underlying surface usually consists of granulation tissue.

With wet gangrene the initial lesion is moist and oozing, and the affected area is swollen, raised, discolored, and cold. Separation occurs at the margin, and the affected skin may slough before it dries; the underlying surface is raw and weeping. Because wet gangrene is in most cases accompanied by infection with saprophytic pathogens, affected tissue often has a putrid and rotten aspect and odor. Systemic disease may result from absorption of toxic products from tissue breakdown and bacteria, resulting in septicaemia.

The presentation of gas gangrene is discussed under “Malignant Edema.”

DIFFERENTIAL DIAGNOSIS
- Confirmation of the diagnosis is by visual recognition.
- Gangrenous mastitis in cows or ewes.
- Photosensitive dermatitis.
- Claviceps purpurea poisoning.

TREATMENT
Primary treatment requires removal of the etiologic insult.

Supportive treatment comprising the application of astringent and antibacterial ointments may be required in cases of wet gangrene to facilitate separation of the gangrenous tissue and to prevent bacterial infection. Aggressive tissue debridement of necrotic tissue and in severe cases amputation of affected body parts may be required. Systemic antibiotics do not reach gangrenous tissue and to prevent bacterial contamination of unaffected body parts may make them feel quite hard. The skin and hair coat over them are usually normal, although some may leak mucoid contents onto the skin. Epidermoid cysts are lined with skin; dermoid cysts usually contain differentiated tissue such as sebaceous glands and hair follicles; dentigerous cysts contain teeth or parts of them. Acquired cysts include apocrine, sebaceous, and keratin varieties.

Developmental cysts, which are present from birth, are usually located at specific anatomic sites, and include the following:

- Branchial cysts in the neck, formed from an incompletely closed branchial cleft
- Fallopian nostrils in horses
- Wattle cysts in goats

Cysts may occur anywhere on the body, but most commonly they are found near the dorsal midline. In horses a common site is the base of the ear.

Other diseases that cause cutaneous abscesses in horses include collagenolytic granuloma, mastocytosis, amyloidosis, lymphoma, sarcoidosis, and infestation with Hypoderma spp.

Surgical excision for cosmetic reasons is common practice.

GRANULOMATOUS LESIONS
OF THE SKIN
Granulomatous lesions are chronic inflammatory nodules, plaques, and ulcers; they are cold, hard, and progress slowly, often accompanied by lymphangitis and lymphadenitis. In many cases there is no cutaneous discontinuity or alopecia. Some of the common causes in animals are as follows.

Cattle
- Bovine farcy caused by Mycobacterium avium and Mycobacterium caprae
- Actinobacillosis (botryomycosis) caused by Actinobacillus lignieresi
- Infections in all species with Corynebacterium pseudotuberculosis, infections in lambs with Histophilus somni or Pseudomonas pseudomallei.

Extension
Abscesses may originate by extension from lesions of furunculosis, pyoderma, or impetigo or by contiguous spread by contact from an internal organ (e.g., from traumatic reticuloperitonitis).
Non-Infectious Diseases of the Skin

INSECT BITE HYPERSENSITIVITY IN HORSES (EQUINE SEASONAL ALLERGIC DERMATITIS)

Insect bite hypersensitivity (IBH) is an intensely pruritic dermatitis of horses caused by hypersensitivity to insect bites, especially Culicoides spp. and, less frequently, Simulium spp.

ETIOLOGY

The disease is caused by type I (immediate) hypersensitivity to salivary antigens introduced into the skin by the bites of sandflies and other insects. There may be a lesser role for type IV (cell-mediated) hypersensitivity in the disease. Culicoides brevitarsis is the cause in Australia, Culicoides pulicaris in the United Kingdom and Europe, and Culicoides obsoletus in Canada. Stomoxys calcitrans, the stable fly, and Simulium spp. cause the disease. The distribution of the skin lesions and seasonal nature of the disease are related to the feeding habits of the inciting insect. For instance, C. pulicaris has a predilection for landing at the mane and tail, and this is where the lesion is most commonly seen.

EPIDEMIOLOGY

The prevalence of the disease varies depending on environmental factors, and possibly characteristics of the local horse population. Up to 60% of horses are reported to be affected in areas of Queensland, Australia; 22% in Israel; and 18% of Icelandic horses in Norway. The prevalence in Switzerland is very low in regions above 1000 m and 1.6% in lower areas. The prevalence of the disease in Dutch Shetland Ponies (>7000) assessed over 3 years was 8.8%.1 The disease is quite common worldwide in areas where hot and humid summer weather favors the causative insects: Sweden, the United Kingdom, Japan, Israel, Hong Kong, North America, Australia, the Philippines, India, and France. Most cases occur during summer, and lesions disappear during cooler weather. Lesions disappear when the horses have been stabled in insect-proof barns for several weeks or are moved outside the geographic range of the inciting insect.

The disease is characterized sporadically and affects only a few of a group of horses. However, because the predilection to the disease is inherited, there may be multiple cases among related animals on a farm. The prevalence of the disease increases with age; 3.4% of Icelandic horses 1 to 7 years of age compared with 32% of horses older than 14 years were affected.

The disease has not demonstrated genetic basis in some breeds, including heritability of 0.08 (standard error [SE] = 0.02) on the observed binary scale and 0.24 (SE = 0.06) on the underlying continuous scale in Dutch Shetland ponies.1 Variants in the major histocompatibility complex (MHC) class II region are associated with disease susceptibility, with the same allele (COR112:274) associated with the disease in Icelandic ponies and Exmor ponies. In addition, homozygosity across the entire MHC class II region is associated with a higher risk of developing the disease (p = 0.0013).2 Genes not encoding MHC and associated with IBH in Old Kaldruby horses include interferon gamma (IFNG), transforming growth factor beta 1 (TGFBI), Janus kinase 2 (JAK2), thymic stromal lymphopoietin (TSLP), and involucrin (IVL).3 Expression of genes associated with allergy and immunity in the skin of affected horses indicates a role for these pathways in the disease.

PATHOGENESIS

Reaginic antibodies (IgE) produced in response to exposure to proteins in insect saliva bind to mast cells in the skin; when exposed to the antigen, they are associated with degranulation of the mast cell. Horses with IBH have IgE antibodies that react with constituents of the salivary gland of Culicoides spp., whereas horses that do not have the disease have IgG, but not IgE, antibodies against Culicoides spp. salivary gland antigens. Horses that have not been exposed to Culicoides spp. do not have either antibody to the insect salivary gland antigen. IgE antibodies against Culicoides spp. are present on a seasonal basis in horses that do not have evidence of the disease, indicating that the presence of these antibodies, although necessary for development of the diseases, is not sufficient and that other factors are involved.4

The antigen in saliva of Culicoides spp. and Simulium spp. has identical IgE epitopes, demonstrating that the disease in some horses is caused by IgE-mediated cross-reactivity to homologous allergens in the...
saliva of both species. A specific antigen in midge (Culicoides sonorensis) saliva associated with IgE reaginic antibodies and causing both in vivo and in vitro activity mimicking IBH is a 66 kDa protein referred to as Cul s 1.

Degranulating mast cells and intradermal or subcutaneous lymphocytes release various vasoactive substances and cytokines that cause inflammation and accumulation of eosinophils in the skin of affected areas and eosinophilia. The distribution of the lesions on patients reflects the insects’ preferred feeding sites. Ponies with seasonal allergic dermatitis have greater numbers of circulating CD5+ and CD4+ T lymphocytes than do normal animals. Increased numbers of CD3+ T lymphocytes, most of which are CD4+, and eosinophils are present in the skin of affected ponies after injection of Culicoides antigen. Furthermore, in equine and monocyte chemoattractant protein (MCP) 1, but not MCP-2 or MCP-4, mRNA expression is upregulated in skin biopsies of sweet itch lesions, demonstrating a mechanism for accumulation of eosinophils and T-2 lymphocytes in the lesions.

**CLINICAL FINDINGS**

Lesions are usually confined to the base of the tail, rump, along the back, withers, crest, poll, ears, and, less commonly, ventral midline. In severe cases the lesions may extend down the sides of the body and neck and onto the face and legs.

Pruritus is intense, especially at night, and the horse scratches against any fixed object for hours at a time. In the early stages, slight, discrete papules, with the hair standing erect, are observed. Constant scratching may cause self-mutilation, severe inflammatory lesions, and loss of hair. Scaliness and loss of hair on the ears and tail base may be the only lesions in mildly affected horses.

**CLINICAL PATHOLOGY**

Affected animals have eosinophilia and thrombocytosis.

**Diagnosis** is facilitated by skin biopsy, fungal culture, parasitologic examination of skin scrapings, and intradermal sensitivity testing. Skin biopsy of early lesions, before trauma masks the true picture, reveals edema, capillary engorgement, and eosinophilic and mononuclear perivascular infiltration. Fungal culture and parasitologic examination of skin scrapings are useful only in that they rule out dermatophytosis, onchocerciasis, and strongyloidosis. Intradermal skin testing demonstrates immediate and delayed sensitivity reactions to extracts of Culicoides spp. and Stomoxys spp. Recommended concentrations of insect antigen in the testing solution are 60 to 250 PNU per mL, or 1:1000 w/v concentration of Culicoides spp. extracts relevant to the locality, providing useful support for a clinical diagnosis of equine insect hypersensitivity.

Testing of serum for specific IgE antibodies holds potential for enhancing diagnostic strategies, but because of the detection of IgE antibodies against Culicoides spp. and Simulium spp. antigens in healthy horses, the poor concordance between results of skin hypersensitivity testing and serum IgE concentration, and the poor performance of serologic testing with enzyme-linked immunosorbent assay (ELISA) that uses the high-affinity IgE receptor (Fc epsilon R1 alpha), serologic testing is currently not recommended.

**DIFFERENTIAL DIAGNOSIS**

Infection with larvae of Onchocerca spp., Strongyloides spp., or Dermatophilus congolensis can produce similar lesions. Alopecia of the tailhead may be caused by Oxyuris equi.

**TREATMENT**

The principles of treatment are removal of the inciting cause and suppression of the hypersensitivity reaction.

Removal of the inciting cause is achieved by preventing horses from being exposed to the inciting insects. This can be achieved by relocating the horse to a geographic region where the insects do not occur, stabiling of the horse in an insect-proof stable during the periods of the day (early evening) when the insects are most active, or applying agents that kill the insects or otherwise prevent them from alighting on and biting the horse.

Suppression of the immediate hypersensitivity reaction or its sequelae can be achieved by administration of corticosteroids (prednisolone, 1 mg/kg orally every 24 hours initially, then reducing to as low as a maintenance dose as possible)

Hyposensitization (allergen-specific immunotherapy) has received attention for its potential efficacy in desensitizing affected horses. Two controlled clinical trials did not demonstrate a beneficial effect (although the placebo effect on the owners was impressive) in a representative sample of horses. These trials were blinded and used objective measures of efficacy. A retrospective study using owner-reported responses (reduction in antipruritic therapy) found a response in 57% of horses. There is insufficient high-quality evidence to support use of allergen-specific immunotherapy as routine treatment for IBH.

**CONTROL**

Reduce Exposure to Biting Midge

Horses should be housed in insect-proof buildings or, at a minimum, buildings that limit exposure of horses to midges by closure of doors and covering of windows with gauze. Impregnation of gauze with an insecticide further reduces biting rates. Stables should be situated in areas that have minimal midge populations, such as on hilltops or well-drained sites. Midge numbers on individual farms should be reduced by habitat alteration, so that areas of damp, organically enriched soils are eliminated. Widespread use of insecticides is unlikely to be environmentally acceptable.

The feeding pattern of midges is such that housing of horses during the crepuscular periods and at night will significantly reduce biting rates and likelihood of infection. Horses kept at pasture should have insect repellents applied regularly and especially to provide protection during periods of high insect-biting activity. Diethyltoluamide, or DEET (N,N-diethyl-meta-toluamide), is the only commercially available repellent with documented activity against Culicoides spp. Application of deltamethrin (10 mL of 1% solution) to the skin of horses did not reduce the frequency of midge feeding in an experimental trial in the United Kingdom. Installation of alphacypermethrin-impregnated mesh in jet stalls reduced the attach rate of Culicoides spp. by 6- to 14-fold and markedly reduced the number of Culicoides spp. insects collected from horses housed in the stalls compared with sentinel horses, suggesting that this might be a useful means of reducing exposure of housed horses to midges.

**SEASONAL ALLERGIC DERMATITIS OF SHEEP**

A disease similar to seasonal dermatitis (insect bite hypersensitivity) of horses (see “Equine Seasonal Allergic Dermatitis” in this chapter) occurs in sheep in the United Kingdom, Brazil, Israel, and likely elsewhere. The disease is also reported in goats in Brazil and suspected in New World camelids (alpacas) in New York State. Up to one-third of a sheep flock can be affected, with the disease remitting and affected sheep appearing to fully or almost fully recover during the dry season in Brazil, or during winter in higher latitudes. Because of the seasonal appearance of the disease during periods
when midges are present or most active, a cutaneous sensitivity to *Culicoides* spp., especially *C. obsoletus* in the United Kingdom or *Culicoides insignis* in Brazil, is suspected.\(^4\) Cutaneous sensitivity to ground-up *Culicoides* spp. is present in affected sheep, and observed bites by *C. insignis* in sheep in Brazil caused pruritus.\(^6\) Allergic dermatitis occurs in sheep infested with fleas (*Ctenocephalides* spp.), although rarely are sheep infested by fleas.\(^2\) Similar skin lesions can occur in sheep infested with lice (*Bovicola ovis*) or scabies (*Psoroptes ovis*).\(^7\) The equivalent disease in horses has a genetic basis, and this should be considered in sheep.\(^2,9\)

The lesions are similar to those in horses and are located principally on the teats, udder, and ventral midline, but also on the tips of the ears, around the eyes, and on the nose and the lips (Fig. 16-1). Initially there is erythema and small red papules followed by development of alopecia and crust formation. The skin of the affected sheep is whitish and irregularly thickened, with alopecia, crusts, and intense pruritus. Histologically the lesions represent the changes characteristic of immediate (type I) hypersensitivity, evident as perivascular eosinophilic dermatitis.\(^8\) Histologic lesions of the epidermis are hyperkeratosis, acanthosis, hypergranulosis, and moderate spongiosis with infiltration of the dermis by eosinophils, macrophages, and plasma cells. There are no diagnostic changes in the differential blood count. Treatment, if provided, should include topical or systemic administration of antihistamines or corticosteroids, although both might be restricted for use in food animals, and there is no formal evidence of efficacy. Affected animals recover when they are not exposed to midges.\(^1\) Control is based on preventing or minimizing exposure to midges.

A very similar disease occurs in cattle in Japan. It is thought to be a result of an allergy to the bite of an external parasite.

**ANHIDROSIS (NONSWEATING SYNDROME, PUFF DISEASE, DRY COAT)**

Anhidrosis refers to the reduced or absent capacity to produce sweat. It affects horses and cattle. Reduced ability to sweat affects horses in hot and humid climates. Affected horses are unable to maintain their body temperature within safe limits, especially during or after exercise, and suffer heat stress and a reduction in athletic performance. The only effective treatment is to move the horses to a cooler environment.

**ETIOLOGY**

The etiology of anhidrosis is unknown, but it involves a reduction in the sensitivity of the sweat gland to β-2 adrenergic stimulation, the normal stimulus for sweating in the horse. Hypothyroidism does not contribute to anhidrosis, although anhidrotic horses have an exaggerated thyroid-stimulating-hormone response to administration of thyroid-releasing hormone.\(^1\) The etiologic or pathogenic importance of this observation is unclear.

**EPIDEMIOLOGY**

The disease occurs in horses, and rarely in cattle, in countries with hot, humid climates, including tropical and semitropical regions.\(^4\) The overall prevalence in horses is approximately 2% to 6% in Florida, with the highest prevalence in southern Florida (4.3%) and lowest in northern Florida (0.08%).\(^2\) The prevalence of affected farms is 11%. There is no reported sex or color predilection. Thorouggbred horses and Warmblood horses in Florida are 4.4 (95% confidence interval [CI] 1.2 to 15.5) times and 13.9 (2.5 to 77.5) times as likely to have the disease as are Quarter horses.\(^2\) None of 190 Arabian horses were affected.\(^2\) Horses with a family history of the disease are approximately 6 times more likely to be affected.\(^2\)

Both native and imported horses are affected, although horses born in the western and midwestern United States are at 2.5 times the risk of developing the disease as are native-born horses.\(^2\) Among native horses, the age of onset of the condition ranges from 1 year to 10 years. Foals, especially of draft breeds, can be affected. Horses imported to endemic areas usually do not develop the disease within 1 year. The incidence and severity of the disease are highest in the hotter season, with most affected horses first exhibiting signs of the disease in the summer.\(^2\)

The disease is rarely fatal unless severely affected horses are exercised in the heat, in which case death from heat stroke can occur. The major importance of the disease is the inability of affected horses to exercise and compete in athletic events.

**PATHOGENESIS**

Sweat is produced in horses by apocrine sweat glands that have a single type of secretory cell. The sweat glands are epithelial (associated with a hair follicle) and have a density of about 800 per square centimeter, with a greater volume density of sweat glands in the summer compared with winter, in skin of healthy Thoroughbreds.\(^3\) Evaporation of sweat is responsible for elimination of approximately 70% of the heat load of exercising horses (with a further ~20% attributable to evaporation from the respiratory tract).\(^4\) Evaporation is essential for heat transfer because the latent energy of evaporation of 1 mL of water is 2.260 kJ/kg (2260 cal/kg of water). High heat transfer from the horse to the environment is possible because of the high sweating rate of strenuously exercising horses of up to 3300 g per meter square of skin surface area per hour or 10 to 12 liters per horse per hour.\(^4\) The sweat of horses during exercise is alkaline (pH 8.0 to 8.9), is slightly hyperosmolar compared with plasma (290 to 340 mm Osmol), and has sodium concentrations that approximate those of plasma, potassium concentrations approximately 10 times those of plasma, and chloride concentrations double those of plasma.

The sweat glands are well innervated, and sweating is controlled by a combination of hormonal (β-2 adrenergic) and neural factors.\(^5\) The apocrine sweat glands respond in vitro to both purinergic stimuli, including adenosine triphosphate (ATP), adenosine diphosphate (ADP), and uridine triphosphate (UTP), and application of isoprenaline, a β-agonist.\(^6\) Both β-adrenoceptor and purinergic receptors are present on the basolateral aspects of the sweat glands, but not the apical aspect.\(^7\) Responses to isoprenaline or purinergic stimulants by sweat glands of anhidrotic horses are much reduced compared with those of sweat glands from unaffected horses.\(^7\) The defect in sweating of anhidrotic horses is a consequence of failure of the gland to respond to either of the agonists for sweat production. This breakdown of cellular secretory function is thought to be the prime cause of lack of sweating, as opposed to earlier suggestions of obstruction of the sweat gland duct.\(^8\)

Sweat production increases with increasing concentrations of epinephrine in blood up to a peak value, after which sweating rates decline. Anhidrotic horses have lower initial and peak rates of sweat production and lower overall sweat production than do normal horses during intravenous (IV) infusion of epinephrine.\(^7\) Suggested, but unproved, mechanisms for decreased sweat production by anhidrotic horses includes diminished glandular sensitivity to epinephrine, failure
of secretory function, blocking of sweat gland ducts, fatigue of the gland, and gland atrophy.

Gaining is the predominant means by which horses dissipate heat. Reduction in the capacity to produce sweat results in an inability to effectively control body temperature during exercise and when temperature and humidity are high. The elevation in body temperature results in tachypnea in an attempt to dissipate heat through the respiratory tract. Hyperthermia impairs performance and, if severe, can result in heat shock, a systemic inflammatory response syndrome, and death.

**CLINICAL FINDINGS**

The most apparent clinical sign is lack of sweating in response to an appropriate stimulus, such as exercise. In severely affected horses, sweating is limited to the perineum, brisket, and areas under the mane and saddle. Less severely affected horses have a diminished sweat response and do not later during exercise. The skin becomes dry and scurfy and loses its elasticity, and there may be alopecia, especially of the face. Affected animals become extremely tachypneic when heat stressed, leading to the colloquial term for the disease, “dry puffer.” Affected horses have abnormally high respiratory rates after exercise that persist for at least 30 minutes after 30 minutes of lunging exercise. Aortic horses have a respiratory rate twice that of healthy horses after exercise (60 bpm vs. 120 bpm). The animal’s appetite declines, and it loses weight. Athletic performance is severely compromised. Affected horses have higher body temperatures during exercise than unaffected horses, and this has not been a consistent finding among studies.

**NECROPSY FINDINGS**

There are no characteristic gross lesions at necropsy. Histologic examination of the skin of affected horses reveals abnormalities in sweat gland morphology, including flattening of cells, loss of luminal microvilli, and a reduction in the number of secretory vesicles. These findings are thought to be a consequence, rather than a cause, of the disease.

**TREATMENT AND CONTROL**

There is no specific treatment that restores the horse’s ability to sweat, other than movement to a cooler climate. Affected horses for which translocation to a cooler environment is not feasible benefit from housing in air-conditioned stables so that exposure to high ambient temperatures is minimized. Exercise of affected horses during the coolest periods of the day is sensible. Affected horses are frequently administered electrolyte supplements, but these are without demonstrated benefit. However, as with all working horses, an adequate intake of sodium, potassium, and chloride should be ensured.

Administration of thyroid hormone supplements is not warranted and might be dangerous because they cause an increase in the metabolic rate, and therefore heat production, of affected horses. Vitamin E administration has no demonstrated efficacy. Removal of affected animals to cooler climates is often necessary, although air-conditioning of stables and maintenance of horses in higher country where they can be returned after a day’s racing may enable susceptible horses to be kept locally.

**WETNESS (MACERATION)**

Frequent exposure to wetting, sufficient to keep the skin permanently wet for long periods, results in maceration with loss of dermal integrity and predisposes to blister formation in sheep and myotic or bacterial dermatitis in all species. In horses it leads to a superficial dermatitis along the dorsum, especially over the croup, and is known as scald. Frequent immersion of the lower limbs of cattle on irrigated pasture causes dermatitis on the backs of the pasterns, leading to mycotic dermatitis. Digital dermatitis of cattle can be induced by prolonged wetness of the skin, resulting in maceration, and inoculation with Treponema spp. Wetting also predisposes to hyperthermia in the young.

Standing in cold water for a period of more than 3 days causes the immersed parts to become edematous and congested and slough their skin in the form of a cuff around the limb. Recovery is slow and incomplete.

**COCKLE**

Cockle is a superficial nodular dermatitis of sheep recorded only in New Zealand that results in nodules in the skin that are of economic importance to the leather industry. The presence of cockle downgrades the value of the pelt, which is rendered unsuitable for suede and clothing.

Cockle is not usually diagnosed clinically, but examination by close inspection of the skin over the upper shoulder region after close shearing has high specificity for detection. The lesions are the result of an immune response in some sheep to infestation with the biting louse B. ovis. The occurrence of cockle and its severity are positively correlated with the severity of the louse infestation, and sheep that develop lesions have B. ovis–specific homocytotropic antibody. Serum histamine concentrations are significantly higher in louse-infested lambs than louse-naïve lambs.

Lesions commence on the neck and shoulders and may extend over the entire pelt. Widely distributed lesions, termed scatter cockle, are attributed to infestation with B. ovis, and this is the most common cause, but rib cockle may be a hypersensitivity to infestation with the sheep ked Melophagus ovinus. Pelt lesions in the dorsal midline region are usually a result of infection with D. congolensis.
CONTROL
Control rests with the control of *B. ovis*. For cockle control, sheep should be treated off-shears with pour-on or spray-on insecticide and, as soon as practical after shearing, treated by saturation dipping. Saturation dipping is required to significantly reduce louse populations. Prelambing dipping is also recommended to reduce the risk of lambs acquiring louse infestations.

WOOL SLIP, WOOL LOSS
Wool slip is a condition in which housed ewes, shorn in winter, lose part of their fleece and develop bald patches over a large area of the rear half of the back. This commonly starts at the base of the tail and progresses to the rump and back and less commonly the neck. There is no systemic disease; the skin is normal. Histologic examination of skin biopsies shows that in affected sheep, the wool follicles are in the active anagen stage rather than the inactive telogen phase of unaffected cohort sheep, and the wool regrows immediately following loss. The loss of wool starts 2 to 3 weeks after shearing. All breeds are equally susceptible, and there is no effect of age or whether the sheep are carrying single or twin lambs; up to 40% of a flock may be affected. The wool loss occurs because of a premature and synchronized shedding of wool fibers and not because of a pathologic process that damages the wool fiber. Wool shedding can be induced experimentally by prolonged treatments with corticosteroids, and the current explanation for the wool shedding that occurs with the wool-slip syndrome is that blood corticosteroid levels rise after the stress of shearing and are maintained for a long period because of the trauma of being housed and shorn and kept in the cold. Blood zinc concentrations in sheep affected with wool slip are within the normal range, and there is no epidermal change as occurs in zinc deficiency.

The prevention of the condition is aimed at reducing the severity and length of the stress period by shearing the sheep at the time of entry to winter housing and ensuring a good nutritional plane in the postshearing period. This hypothesis as to cause may not be correct because the syndrome has also been seen in the summer in Wiltshire shorn sheep that had little history of stress in the period immediately preceding the wool slip.

Wool slip should not be confused with the normal shedding of wool that occurs in breeds such as the Wiltshire or Shetland in the spring period. Loss of wool along the backline also occurs in older longwool sheep and may be exacerbated by lambs playing or sleeping on the ewe.

Impairment of wool growth and a thinning of fiber diameter can occur during the course of any severe disease, such as blue-tongue, pregnancy toxemia, or footrot, temporarily affecting the growth of the fleece. This results in a segment of the wool fiber that has decreased tensile strength, and the condition has the name *tender wool*. Following recovery from the inciting disease the wool growth is normal, but there is a line of wool with poor tensile strength in the staple. This can be observed in the intact fleece as a line of decreased fiber diameter, often with a change in crimp character and discoloration as a result of entrapment of dust. The wool may break if the staple on either side of this break is sharply snapped between the fingers. The fleece may subsequently be shed in part or in whole at the level of the defect, a condition known as wool break. Tender wool downgrades the value of a fleece and has economic significance in wool-producing sheep.

Zinc deficiency can reduce keratinization, reduce wool growth, and occasionally result in fleece loss in sheep. Wool loss associated with pruritus occurs in association with external parasite infestations and with scrapie and pseudorabies in ruminants.

Pelodera dermatitis, characterized by thickening of the skin and complete wool loss in affected skin areas, has been recorded in winter-housed sheep where there was poor bedding management. The condition affected the majority of the ewes at risk. The parasite *Pelodera (Rhabditis) strongyloides* is a free-living nematode commonly present in decaying organic material but can invade hair follicles to produce an inflammatory response. Histologic examination of the skin showed the presence of the parasite in wool follicles and infiltration of eosinophils and mast cells in connective tissue. Affected skin areas were those that had contact with the bedding when the sheep were lying down, and large numbers of the nematode were found in the bedding. Clinical signs regressed with the more frequent provision of new bedding and disinfection of the stable.

WOOL EATING
Wool eating can occur as a result pica associated with micronutrient deficiency. A condition called *shimao zheng*, occurring in a region of the Gansu province of China, has wool eating as its primary manifestation. The disease has a seasonal occurrence, with the peak incidence in January through April. Both goats and sheep are affected, but the incidence and severity are much higher in goats, where 90% may show signs. Affected animals bite the wool or hair off their own or other animals’ bodies, particularly in the hip, belly, and shoulder areas. Histology on biopsies shows heavily keratinized epithelial cells, a decreased number of hair follicles, and aggregated foci of lymphocytes in the dermis. Controlled trials have shown that the condition can be corrected by supplementation with sulfur, copper, and iron. Wool eating is also recorded in Israel, possibly associated with trace-element copper and zinc deficiency, and in housed superfine Merino sheep in Australia fed grain-based supplements, where it is corrected by the provision of roughage in the form of hay. Wool and hair loss in individual sheep and cattle in association with excessive licking have been recorded and are postulated as psychogenic dermatoses.

IDIOPATHIC NASAL/PERIORAL HYPERKERATOTIC DERMATOsis OF CAMELIDS (MOUTH MUNGE)
Idiopathic nasal/perioral hyperkeratotic dermatosis is a common skin condition of llamas and has anecdotally been reported in alpacas. The ailment is characterized by a thickening of the stratum corneum of the epidermis resulting in hyperkeratotic plaques and crusts in the perinasal and perioral region. Similar skin lesions may occur on the perineum, ventral abdomen, medial hind-and forelegs, axillae, and inguinal region, in which case the condition is more globally referred to as idiopathic hyperkeratosis. The etiology of this condition is poorly understood but has been categorized as zinc-responsive dermatosis because cases responsive to high oral doses of zinc have been reported.

CLINICAL FINDINGS
Individual animals of either sex between 6 and 24 months of age are commonly affected. Animals present with thick papular crusts and plaques covering the periocular and perioral area, occasionally obstructing the nostrils. Secondary dermatitis that waxes and wanes is common, but pruritus is usually mild or absent.

CLINICAL PATHOLOGY
The diagnosis is based on clinical presentation and by ruling out other differentials. Histologic examination of skin biopsies shows epidermal and follicular orthokeratotic hyperkeratosis that can be associated with dermal infiltration with lymphocytes, macrophages, and occasionally eosinophiles. The degree of infiltration is dependent on the extent of secondary inflammation. The treatment outcome of diagnostic therapy consisting of oral zinc supplementation will

**TREATMENT**

Supplementing the diet with zinc, either by offering zinc-enriched feed or by supplementing organic or anorganic zinc, for a minimum of 2 months has been suggested. Current recommendations are to supplement either zinc sulfate (2 g/d and animal) or zinc methionine (4 g/d and animal) for a period of 2 to 3 months before reassessing the patient to determine the treatment effect.

Treatments targeting at resolving secondary dermatitis consist of local and/or systemic administration of antibiotics. The topical use of a 7% iodine tincture to control secondary dermatitis and of chlorhexidine-based shampoo loosens hyperkeratic crusts has been recommended. The use of topical or systemic glucocorticoids has been proposed in cases not responsive to antibiotic therapy.

**Bacterial Diseases of the Skin**

**METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS**

Staphylococcal skin disease in animals is not uncommon and includes udder dermatitis in cattle; secondary infections to chorioptic mange or orf in goats (may also be *S. chromogenes* and occasionally *S. hyicus*); dermatitis of the head in sheep; and in pigs, usually *S. hyicus* but also possibly *S. rostrri, S. pasteuri, S. hominis, S. warneri, S. homolyticus, S. epidermidis* (may be methicillin resistant), and *S. chromogenes.*

**INTRODUCTION**

Methicillin (formerly meticillin in the United Kingdom) was introduced into human medicine in the 1950s to treat penicillinase-resistant *S. aureus* (SA).

Methicillin-resistant *S. aureus* (MRSA) strains have an altered protein-penicillin binding protein (PBP2a) that has a low affinity for all beta-lactam antibiotics (i.e., penicillins and cephalosporins). The protein is encoded by the *mecA* gene.

The MRSA strains may also have or not have a penicillinase enzyme (a beta-lactamase). *Spa* typing is a method of typing *S. aureus* based on repeats located on several housekeeping genes.

Multilocus sequence typing (MLST) is a method of typing based on the sequence of several housekeeping genes. Similar sequence types may be grouped together in clonal complexes (CCs).

This protein is encoded by the gene *mecA,* which resides on a mobile genetic element called a staphylococcal chromosomal cassette (SCCmec). The detection of this gene is the best detection for MRSA.

Methicillin is no longer used in human medicine, but oxacillin, nafcillin, and cloxacillin, which are very similar, are still used, although the resistance to these is usually lower than it is to methicillin.

The serious problem is that MRSA organisms are also often resistant to other antimicrobials, in particular aminoglycosides, macrolides, tetracyclines, and fluoroquinolones.

**Human Public Health**

MRSA organisms cause infections, can be carried both persistently or intermittently, can colonize, and can also cause contamination. The infection can be mild or severe and sometimes fatal. There is a wide range of human prevalence in many countries. In some countries, a certain lineage may be most common.

Over the years, the types found in humans will change as new clones arise and they introduce new toxins. The type CC398 is the most common animal type isolated from humans and is associated with increased mortality and morbidity. It also carries endotoxin genes but has only once been associated with food poisoning.

These bacteria have been an important cause of nosocomial infections for over 40 years.

Type CC398 is a poor persistent colonizer of humans. It is also less transmissible than non-ST398 in humans and in Dutch animals.

Very rarely are these large animal-associated MRSA organisms responsible for serious infections in humans, although they have been found in deep-seated infections in skin and soft tissue and in pneumonia and septicemia. However, in most cases these infections with hospital-acquired MRSA (HA-MRSA) are inapparent, except when there is stress, such as in surgical situations or in immunocompromised patients.

A new strain has arisen in the Netherlands with no link to existing established Dutch risk factors for acquisition. In one study, a quarter of the 5545 MRSA isolates were from defined risk groups; 26% were CC398, and 74% were non-CC398. Increases in CC398 have occurred in patients with or without contact with livestock and have led to an increase in carriers and infections.

Over the period from 2002 to 2008, there was a 925% increase in the number of cases in the laboratory database. Most cases involved CC398, with *spa* type 1567 particularly overrepresented in sepsis and post-trauma osteomyelitis. CC398 was also more likely to be multiresistant than other types of MRSA. Simply put, the increase in CC398 has led to more carriers and infections.

MRSA accounts for approximately 20% of all bloodstream infections in U.S. hospitals and approximately 65% of the *S. aureus* infections in intensive care units, and it killed approximately 18,000 Americans in 2005.

**Veterinarians**

The carriage of MRSA by veterinarians in Australia attending a conference in 2009 has been investigated. Industry and government veterinarians had the lowest levels of MRSA carriage at 0.9% prevalence. Those with horses as a major workload had 11.8% prevalence, and those on horse work only had 21.4% prevalence. Veterinarians with a dog and cat practice had 4.9% prevalence.

The conclusion was that MRSA was an occupational hazard for those working in clinical practice in Australia.

A study of veterinarians showed that MRSA and livestock-associated MRSA (LA-MRSA) infection levels were 9.5% and 7.5%,
respective, in Belgium and Denmark (all Danish MRSA are LA-MRSA). A strong association was found with live pigs. At the 2008 meeting of the American College of Veterinary Surgeons, a survey sampled 341 people; 17% of the veterinarians and 18% of the technicians were positive for MRSA. Contact with small ruminants in the previous 30 days, living with a person with MRSA diagnosed in the previous year, and working where there is a person specifically in charge of an infection control program were associated with colonization.

Veterinary students conducting diagnostic investigations were also sampled. Thirty students visited 40 pork farms and found MRSA in 30% of the farms; 22% of the students picked up the infection following exposure, but all were clear within 24 hours of the visit.

Pig Farmers
Thirty-five persons were screened for MRSA and sent on holiday; 27 of the farmers (77%) carried MRSA at least transiently. For 59% of the farmers, the infection was not cleared after the holiday away from pigs.

Butchers
Colonization of butchers with LA-MRSA has been documented in markets in Hong Kong. 300 pork butchers were sampled, and 17 were positive. Although five strains were health-care associated, the high incidence of t899 (CC9) suggests that cross-contamination from pork products occurs quite frequently.

Animal MRSA
Animal MRSA strains are found in farm animals, and it is likely that people in contact with these animals and their families, such as veterinarians, farmers, farm workers, and abattoir workers, may acquire these organisms. In the European Union, there are many animal MRSA types, but the most common type in farm animals is CC398. It is found commonly in pigs, veal calves, and broiler chickens. This type does not appear to be a risk to abattoir workers. There is also no evidence, as yet, that this strain can cause infection or generate carriers in humans when found in food. Where workers work full time, the incidence of MRSA is higher, and less if part time.

In general, the presence of multiple virulence profiles within a MRSA genotype in an animal species suggests possible reverse zoonosis and the potential for new MRSA clones by gaining or losing additional genes.

If the staphylococci are resistant, then treatment with antibiotics to which the staphylococci are resistant can increase the proportion of infected pigs and increase the numbers of bacteria present. Generally, MRSA organisms are poor responders to treatment, and infected patients have a high death rate.

For years, the problem was restricted to hospital (HA-MRSA). These strains were the main group for over 40 years, and they are resistant to many antibiotics. Since then, the incidence of HA-MRSA has decreased and now only accounts for about 20% of all infections, particularly those occurring in intensive care units.

Community-associated MRSA (CA-MRSA) developed in the 1960s, and strains were found outside of hospitals. In particular, these strains were isolated from cats, dogs, and horses and consisted of S. intermedius and S. pseudointermedius. It is now estimated that CA-MRSA may account for about 13,000 infections annually that require hospitalization, with a resultant 1400 deaths.

In 2003, large-animal-associated MRSA (LA-MRSA) strains were discovered. These were largely CC398, as determined by MLST. In different countries various types are found. For example, in Germany CC5, CC9, and CC97 are often found. In a German study of 14,036 MRSA samples, there were 578 spa types. Where there are large numbers of these, such as in pigs, the possibility of colonization and infection rises.

LA-MRSA strains share some virulence factors with human strains, but they also have distinct virulence factors. Exchange of these genes encoding virulence factors may extend the host range and thereby threaten public health.

ETIOLOGY
Three types of MRSA are currently recognized, as described in the previous sections: HA-MRSA, CA-MRSA, and LA-MRSA. Originally, the HA-MRSA strains were most common, then the CA-MRSA strains became problematic as the incidence of HA-MRSA decreased, and currently LA-MRSA strains are receiving increased attention.

The CC398 (ST 398) type is 12 times more likely to be carried by pig farmers than nonfarmers, and cattle farmers are more than 20 times more likely to be carriers. LA-MRSA strains, which do not spread rapidly in the human population, emerged in the 1960s following poor response to treatment. It is now thought that half of the swine herds in Iowa carry LA-MRSA CC398. Pig farmers in Switzerland were found to be carriers of CC398.

LA-MRSA strains were first described in a pig in 2003 and in other species in 2005 and 2007, and since then cases have occurred in several countries. LA-MRSA strains are an important source of infection in humans. It is thought that people spending a lot of time with pigs are at a higher risk of testing positive.

LA-MRSA strains were first noticed as spreading to humans in 2008 and after cases reached hospitals in the Netherlands and Denmark. Pig exposure has been cited as an important factor in LA-MRSA colonization in humans. There is apparent transmission between pigs, pig farmers, and their families. Pig farmers are 760 times more likely to be colonized by LA-MRSA than the general population.

LA-MRSA strains are not typable by pulsed field gel electrophoresis (PFGE) because of the presence of a novel DNA methylation enzyme. For this reason, spa types have been isolated from pigs and their human contacts; however, the majority are classified as sequence type (ST) 398 by MLST, suggesting that ST398 strains are adept at colonizing pigs and can be transmitted between pigs and their human contacts.

MRSA infections spreading from dogs and horses to humans are not usually important causes of infection; they tend to be sporadic and involve human skin infection. In one study, 4 out of 13 workers at a teaching and research farm had MRSA, but a variety of animals (dairy cattle, beef cattle, sheep, hogs, pigs, and goats) did not. A unique sequence was found in pigs in Europe, and it was found that the new MRSA clone ST398 belonged mainly to random spa types 034, 011, and 108. ST398 is considered the main reservoir of LA-MRSA infection, and it is the main type that subclinically affects pigs. The transmission of ST398 to humans is dependent on the intensity of the animal contact, but spread to the local community is not very frequent.

CC398 is the predominant clone in animals. Genes confirming metal resistance are commonly found in CC398, and only a few non-CC398 types carry these genes. This suggests that the use of metal-containing compounds in pig production may aid in the selection for LA-CC398.

EPIDEMIOLOGY
Distribution
MRSA can be found in nearly any location. It has been found in Korea in a variety of forms in pigs (ST398, ST541, and HA-ST72). It has been found in Italy in a slaughterhouse study, suggesting a high risk from pork products. It was found in Sweden in cattle. In the United States, United Kingdom, and Denmark, it has been found in pigs and pig workers. At the equine hospital in Turkey, 48% of the horses, 92.3% of the clinical staff, and 71.4% of the environmental samples were positive for MRSA. In France, three MRSA strains belonging to t034 spa were identified. S. aureus was identified in 59/60 necropsies where staphylococci were implicated, and the organism was associated with 1.7% of the total equine deaths. The other case was associated with S. pseudointermedius.

In a study of veterinary hospital environments, MRSA was found in 12% of the environments. In the small-animal hospital, it was 16%; equine hospital, 4%; and large-animal hospital, 0%. The strain was usually type spa 100, which is commonly found in the United States. MRSA was found in fattening pigs in Germany (152/290), all of
which were ST398 cases. In Belgium, pigs were found to be already colonized in the farrowing house.44 Various strains were found in Japan, including ST398 and ST9; but also ST5, ST97, and ST705.45 In Belgium, 94% of the open farms and 56% of the closed farms were found to be infected,46 and management and age-related trends were found to be important. There is a low level of MRSA incidence in Switzerland.21 In Ireland, MRSA has been found in horses and dogs, but not cats,47 and in three distinct clones (CC5, CC8, and CC22).47

Colonization

Colonization commences at birth, and piglets born to positive sows rapidly become infected; thus, by weaning, all the offspring are positive.48

Subclinical nasal infection is common in pigs.48 In other studies, the prevalence was found to increase rapidly after weaning but then fall during the finishing period,49 and the strains were found to circulate from the nursery unit to the finishing unit. Where there is a doubling ofveal calf, cattle, and pig populations in a municipality, there appears to be an increase of MRSA over the other types of S. aureus in the population.18

Pigs in slaughterhouses were found to be colonized by MRSA in different EU countries.24,29,40,49

Transmission

Air inlets and outlets have been found to be contaminated, contributing to MRSA transmission. Regular airborne transmission of LA-MRSA and deposition, strongly influenced by wind direction and season, up to 300 m was found in MRSA-positive pig farms.50,51 LA-MRSA is regularly found downwind of pig and poultry barns (73% and 44%, respectively) but at low concentrations, suggesting that colonization is unlikely.

In a study in Denmark, MRSA was found in the dust and in five different age groups of pigs.52,53 Inside pig and poultry barns, the levels were much higher. MRSA has also been found in the exhaust air from piggeries. In one study, 85% of all barns had MRSA in the air, and boot swabs and feces were also positive.53

In one study, nine fomites were investigated, and all transmitted MRSA to pig skin, except soap.54 The nonporous fomites were able to transmit to the pig skin many weeks after contamination. In one study it was found that use of mobile phones by healthy workers in the health-care industry raised the possibility of transferring infection to workers, patients, and people outside the hospital.55

MRSA can be considered a contaminant of the environment and has been detected on field surfaces.56 There is a highly significant positive association between nasal carriage of MRSA in animals and the ability to isolate MRSA from dry surfaces.57

Pig workers have a significant risk of transmission.58 Transmission to humans is associated with contact time, which is why workers are more likely to be carriers than the other members of the family. People who visit farms regularly to buy eggs or milk, or even for private farm visits, are more likely to be colonized.

Shower units on conventional swine farms have been shown to be infected.59 MRSA can be isolated at postmortem examinations.60 In a recent study, it was found that pharyngeal tissues had a high level of MRSA and thus may be more important in transmission than was previously thought because nose-to-nose contact with infected pharyngeal tissues is possible.61

In an experimentally induced infection with two sequence types (ST98 and ST9) and four commonly found spa types (011, 018, 034, and 089), it was found to be difficult to produce carriage after nasal/gastrointestinal infection of piglets. Vaginal inoculation of the sow resulted in persistent carriage of 011-ST398 and 089-ST9 in all newborn piglets.62 A low-dose inoculation was shown to be capable of horizontal transmission between pigs.63 The major risk of transmission of ST398 is probably through trading of piglets.64

In a U.S. study in Ohio, 3% of the pigs were found to be positive for MRSA before slaughter, 11% in the lairage, and 2% in the carcasses, along with 4% of the retail pork.65 The most common type was ST5, followed by ST398.

RISK FACTORS

Management is an important factor, although direct transmission is probably the most important. Animal carriers and human carriers present a hazard.

Risk factors also include herd size. The larger the herd, the more likely it is that MRSA is present.

Low incidence at birth is common, which slowly increases and stays positive for weeks, and then the prevalence slowly declines. In one study, 33% of sows were infected before farrowing, but the level had risen to 77% before weaning. Transmission rates were higher in preweaning pigs than in postweaning pigs66 and spread rapidly in weaned piglets.67

There are usually up to three spa types per herd. The sow herd determines the production-chain levels of infection. The level of infection in piglets depends on the sow’s colonization.

In all systems, the prevalence decreases with age.68,69 If a pig herd is positive, people can be positive. If the pigs are positive, then farm dust certainly will be. Environmental contamination is therefore a risk. In one study, MRSA was found in dust, boots, socks, feces, air, and the shower units.70

In dairy herds the use of antibiotics is a risk factor, as are dairy hygiene and the age of the cow population. In pigs, LA-MRSA may persist without the use of antibiotics.71

If there are no positive pigs, then usually there are no positive people.72 Farm visits are associated with the acquisition of MRSA, but most of these cases are only temporary.73 At the 2006 International Pig Veterinary Society (IPVS) conference, 276 pig vets from a large number of countries were sampled, and 12.5% tested positive for MRSA.

On Swiss pig farms, it was shown that SA (including MRSA), endotoxin, and fungi levels were higher in the winter, so there may be a seasonal effect.74 The incidence of MRSA is higher in zinc-treated and antibiotic-treated pigs.75

Pigs

It is generally acknowledged that the pig is the main reservoir for MRSA in large animals. S. haemolyticus is usually present in pigs but differs from S. aureus in that it does not have the mecA gene. Other species in pigs may include S. chromogenes, S. epidermidis, S. sciuri, S. warneri, and S. xylosus. A new species (S. rostris) has been found in the nasal cavity of pigs in Switzerland.76

There is known transfer between pigs and humans,29,34,75,76 but it rarely spreads to the community.77 Under some circumstances, MRSA strains can also produce enterotoxin. MRSA strains have been implicated in swollen ears, umbilical abscesses, vegetative endocarditis, subcutaneous abscesses, foot lesions, arthritis, osteomyelitis, mastitis, metritis, and enteritis.

There is a low incidence of MRSA in the United States compared with Europe. MRSA has been found in pigs in France, the Netherlands, Denmark, and Singapore.24,40,78

In one study of Irish pigs, no cases of MRSA were found, and only two workers tested positive.79 In finishing units in Italy, 11 different spa types were found, and this report identified ST9 for the first time in Europe and ST1 and ST97 for the first time in pigs.80

In Spain, slaughter pigs are commonly affected with CC398 and CC97.81 Free-range pigs in Spain are also infected (CC398 and t011).82 In Belgium, 94% of pigs on open farms were infected, compared with 56% of pigs on closed farms.83 Thus far, in pigs in Europe, ST398 does not seem to be highly resistant to most antibiotics, with the exception of tetracyclines and perhaps macrolides.

The existence of lineages in species has been shown; for example, cattle often have CC133 and CC151, CC5 is common in poultry, and CC8 is common in horses. In pigs, the most common clonal complex is CC398,84 which is different from the HA-MRSA and CA-MRSA in strains in humans.80,84 but CC30, CC9, and CC49 have all been found. There are differences in colonization patterns of the different MRSA types in pigs.85 CC9 is most common in Asia; ST8 has been found on a Norwegian pig.
farm, and the low occurrence suggests that this strain may be less able to colonize and persist on pig holdings. Additionally, there is considerable heterogeneity of the resistance genes in the complex, so CC398 may acquire multiple antimicrobial resistance genes. It easily acquires genetic material, and therefore strains with increased resistance will develop.

ST398 seems to prefer pigs but has no host specificity. The same authors suggested that ST398 has an apparent lack of virulence genes in a unique genetic background. It does not, for example, usually produce Pan-ton-Valentins E leukokoidin.

In a study in the Netherlands, it was found that the MRSA strains were usually resistant to at least three but sometimes five out of six antibiotics. There may be a link with cephalosporin usage in pigs.

In Switzerland, there is a low level of MRSA in pigs, although transfer to humans may happen frequently. This low level is a result of the very low level of antibiotic use for pigs in Switzerland. MRSA ST49 was found in Switzerland, and it has been suggested that it has been selected in the Swiss pig husbandry because a nearly threefold increase was noted over a 3-year period.

MRSA is commonly present in pigs in Denmark as a reservoir, but not in other species. In pigs, it has been shown that 74% of the CC398 strains from Denmark had a reduced susceptibility to zinc chloride, which is important as a reflection of the use of zinc oxide to prevent Escherichia coli scours.

In a study of slaughterhouse pigs in Switzerland, it was found that 89% of farms screened were positive for SA. Although no MRSA strains were found, there was widespread antimicrobial resistance, particularly to penicillin (62.5%) and tetracycline (33.3%). The S. aureus isolates belonged to Ridon spa types 034, 208, and 899.

In a large study of herds in the Netherlands (202 pig farms), MRSA was present in 67% of the breeding herds and 71% of the finishing herds. MRSA was found in 40% of small herds and 80% of the larger herds.

A study in pigs and people in Canada in 2008 showed that 45% of the farms were affected, but only 24.9% of the pigs and 20% of the farmers. The most common type was the same as that found in Europe, CC398 of spa type 539 (Ridon 034). The same strains were found in the pigs and personnel on the five farms where human colonization was present.

A pig can be colonized with several strains at any one time.

Cattle

MRSA has been associated with mastitis in cattle. In a Belgian study, the presence of meCA was investigated in 118 MRSA strains from 118 different farms with S. aureus mastitis, and MRSA was found in 11 samples; all were CC398 (1011 or f567). Non S. aureus MRSA strains have also been studied in veal calves, dairy cows, and beef cattle, and most of the organisms were S. sciuri, S. lentus, S. fleurette, and occasionally S. epidermidis.

In a long-term study of MRSA ST1, t127, mastitis in a dairy cow was reported.

The first isolations from bulk-tank milk in the United Kingdom were described in 2012, and in these strains a meCA homologue was described. In a subsequent study of UK cattle veterinarians, only 13/307 delegates were positive for MRSA, and none had the meCA homologue. MRSA has been found in milk from the udder in Switzerland and at high levels in milk in Africa. It was found to be present at quite high levels in Iran (28%), but at low levels in India and Japan. It can invariably be found on the skin of the udder and the inside of the teat. Generally, in Europe, the United States, and Canada, the level of MRSA in cattle is quite low. In a study of U.S. bulk-tank milk samples, only 4% had MRSA (6/150). The most common MRSA strain is generally CC398, but there may be more than one strain of different types on the same farm, which suggests that subtypes may have been imported onto the farms or that a strain of CC398 has undergone diversification.

In one study, 88% of dairy farms had MRSA (90/102), 458/2151 (28%) of the cattle were positive, 32% of the farmers were positive, and only 8% of the family members were positive; the prevalence in the humans decreased in the vacation periods. A novel meCA homologue has been found in humans and cattle in Denmark. In a study in Denmark, a new meC gene was discovered. In a study of 411 cows, it was found that 3.9% had MRSA, and all were positive for meCA, negative for meCC, and negative for Panton–Valentine-leukokidin (PVL). The MRSA-positive level was much lower than in Dutch pigs and veal calves.

In a study of 36 German dairy herds, CC398 strains were found in all 36; no PVL genes were detected, but a hemolysin gene was found. In another German study, it was found that where dairy cattle were kept in an area with a large number of pigs, the MRSA level was approximately 2%; where there were no pigs, the level was less than 1%. In the Netherlands, in a study during 2008 to 2009, over 50,000 milk samples were examined from 14 different dairy herds, and only 14 MRSA strains were found. All were CC398 and the usual spa types (f011, t108, and f889) commonly found in pigs. Not all of the strains possessed PVL genes, and all were resistant to two or more antibiotics.

In the United Kingdom, a study of S. aureus in milk samples showed that 31/940 were resistant to cefoxitin and/or oxacillin, and 3/24 tested positive for the novel meCA variant. This variant is 70% homologous to the meCA gene, and it is located on a newly recognized SCC meCA element designated SCC meC61. Most isolates were MLST 1245, CC130, and spa type f843.

A study showed the correlation between MRSA in humans and the percentage of positive cows in a herd; 36% of human nasal swabs and 61% of bovine nasal swabs were positive. In addition, 44% of bulk milk tests were also positive.

A new type showing resistance to cefoxitin and/or oxacillin has been detected in bulk milk and mastitis cases in England and Wales and also in humans from England and Denmark. The isolates are negative for the meCA gene and in latex agglutination tests for PBP2, encoded by meCA in standard tests. This new variant meCA gene was found in 13/940 samples examined. Most of these isolates were MLST 1245, CC130, and spa type f843.

In a study of beef cattle in the United States, MRSA was not isolated from 491 nasal swabs and 488 fecal samples.

Veal Calves

In a study in veal calf farms, it was found that 38% of farmers had MRSA, and 16% of family members also had MRSA. Carriage was related to contact, and a family member was more likely to be positive when the farmer was positive. Only a small percentage consisted of persistent carriers, and only 7.5% were not CC398.

In a study of rose and white veal calves, it was found that rose veal calves had less MRSA than white veal calves, and the conclusion was that care had to be gene taken in the use of antibiotics. Conversely, it has been suggested that MRSA increased in calves with the length of the production cycle but was not related to antibiotic use.

A high carriage rate of LA-MRSA was found in Belgian veal calves compared with other farm types, and they were significantly more resistant to antibiotics than the pig strains. Most were CC398 in the multispecies survey, but MRSA CC130 and CC599 carrying the meCC gene were detected in the beef and dairy cattle.

Sheep and Goats

S. aureus is widely carried in sheep and goats and shows considerable diversity. It has been isolated from goats with mastitis. In a study of 179 sheep, 41% were positive; in a small sample of goats, 11/17 were positive. Twelve ST types were found and 26 spa types. Most commonly these were ST133. Only three MRSA strains were found in all of the positive strains, and two were ST130 and 1 ST398.

Small Animals

MRSA was first recognized in dogs and cats in the United States. In pets, the MRSA strains can include a number of species, including S. epidermidis, S.
in Europe it is CC398, whereas in Europe it is
CC500, whereas in Europe it is CC398, which is highly prevalent in horses and veterinary personnel at equine clinics.

In the Netherlands, there were no cases of MRSA in 2002, but by 2008 MRSA was found to be present in 375 of the SA samples. The CC398 strain currently predominates (t0111, t2123, and t064).

During an outbreak in a teaching hospital, some of the personnel tested positive, in addition to 57% of the environmental samples, including samples from the students’ and staff members’ rooms. In another study, 81 swabs from 42 horses on four farms were examined, and 11 species of staphylococci were found; 17/42 were untypable.

MRSA was reported in Sweden in 2012, where 8/10 horses were infected in a veterinary hospital and two other infected horses were found close by. In another hospital study, 12/84 horses and 16/139 staff at a veterinary teaching hospital had MRSA. ST5 was the culprit. The risk was greater in the veterinarians and in the full-time rather than the part-time staff.

The first strain of MRSA isolated in horses in the United Kingdom was ST398 from two horses and reported in 2009.

A survey of horses admitted to the Berne University Clinic showed that 2.2% of the horses had MRSA.

It has been found in Lusitano horses at the Lisbon teaching hospital.

In a large study of 209 racehorses, 13 veterinarians, and 14 environmental surfaces, it was found that 48.3% of the equines, 92.3% of the vets, and 71% of the environmental samples were positive for a variety of staphylococcal species.

In another study of nasal swabs from horses, 42 strains of MRSA were found, again from a variety of staphylococcal species (S. sciuri, S. xylosus, S. lentus, S. aureus, and S. capitis). All the species contained the mecA gene.

Other Species

Poultry

People working with broilers have higher levels of MRSA than the general population (5.5% compared with < 0.1%) in the Netherlands. However, the level is lower than in those working with pigs and veal calves. In another Dutch study of broiler flocks, slaughterhouses, and personnel, it was found that the risk was greater when dealing with live animals. Over 36% of the flocks were positive and 6% of the broilers. During the production day the level of MRSA infection increased from 8% to 35%. Most strains were ST398, but there were also large numbers of ST5.

In a study of mixed pig and poultry farms, MRSA was most frequently isolated from the cloaca, nose, pharynx, and skin under the wings. There was a low prevalence in the broilers (0% to 28%) on the farm, but 82% to 92% of the pigs had MRSA. The broilers may be less sensitive to the ST398 strain than pigs. The farmer may have been part of the cause of the spread of the MRSA from the pigs to the poultry on the same mixed farm.

Turkeys

A study showed that 18/120 turkey farms had MRSA, as did 22/59 people on the farms. Those with frequent access were most likely to test positive.

Donkeys

In a study of donkeys in Sicily, 40/46 donkeys were found to be positive for staphylococci. Of the 80 isolates examined, 52/80 were S. aureus. Nine genera were found; most of these were MSSA, and only 14 were MRSA. The mecA gene was found in 6/52 SA cases.

Donkeys could be a reservoir for the CC133 lineage.

Wild Boar

So far no important MRSA cases have been found in wild boar.

Backyard Pigs

A study in the United States of backyard pigs suggested that there were no major differences from domestic commercial pigs, and that in all probability there was no greater risk for human infection from these pigs.

In a study of farms in Connecticut (considered noncommercial) and their pig handlers (263 pigs and 9 humans on 35 farms), it was found that 51% of farms, 30% of pigs, and 22% of the handlers were positive for MRSA. The swine had HA-MRSA, CA-MRSA, and LA-MRSA, but the humans only had HA-strains of MRSA. The PVL gene was found in 7/8 of MRSA isolates, and this was the first time this gene had been found in pigs in the United States.

Camels

MRSA has been described in an alpaca, which was infected with a human epidemic clone.

Fish

MRSA have been isolated from Tilapia. In one study, 559 isolates of staphylococci were obtained; 198 (35%) were S. aureus, and 98 (50%) of these were MRSA.

Zoo Animals

There are few reports of MRSA in zoo animals (skin in an elephant, rumen in a Moufflon, digit of a rhinoceros).

Other Sources

Holding Areas

The abattoir holding area may act as a reservoir for MRSA, but this area does not appear to disseminate MRSA into the processing lines.

Working in a lairage area or in a dehairing area was the major risk factor for MRSA carriage in pig slaughterhouse workers. The overall prevalence is low and decreases along the slaughterhouse line.
The high prevalence of nasal carriage in slaughterhouse workers is largely associated with working with pigs.\(^{144,145}\)

**State Fairs**
A study at two state fairs in the United States showed that only 25/157 pigs (15.9%) were positive for *S. aureus*, and only two MRSA cases were found.\(^{146}\)

**Food**
There is no doubt that MRSA acquired on the farm can be transferred through to processing, but there is no significant evidence of cross-contamination between carcasses.\(^{147}\)

In a German study the contamination rate was highest in nasal swabs at stunning (64.7%) and was low in carcasses (6%), meat at processing (4.2%), and final products (2.8%). MRSA can be identified at all points in the food chain.\(^{148,149}\)

Food may be contaminated by MRSA, but there is no evidence that this leads to increased carriage rates in humans, either in food handlers or the public. It has been found in meat,\(^{150,151}\) and its incidence in meat increased carriage rates in humans, either in food handlers or the public. It has been found in meat,\(^{150,151}\) and its incidence in meat is difficult to control. Hand washing before and after contact is essential, as is avoiding direct contact with nasal secretions, saliva, and wounds. MRSA organisms can be killed with photodynamics.\(^{160}\)

**PATHOLOGY**
MRSA has been detected in less than 1% of all pig postmortems. It is found both as a primary pathogen and as mixed infections, mainly in suckling and weaned pigs. Joints are more often affected than tissues. MRSA organisms live in clusters between the cilia and as singletons on the cilia in the respiratory tract. There are no morphologic changes when pig tracheal explants are experimentally infected. In an experimental infection,\(^{152}\) there was colonization of lymph nodes (ileocecocolic).

**DIAGNOSIS**
MRSA organisms can be identified by phenotypic methods or genotyping. Samples are taken directly from lesions, biopsies, or blood culture onto selective and nonselective media. Contamination can be detected by swabbing noses (individuals), sampling dust (in herds and flocks), and food sampling. Increased sensitivity is obtained when using selective liquid enrichment media. Spa typing is available for lineage studies.\(^{158}\)

Diagnosis of MRSA is based on culture, colony morphology, MLST on the protein A gene sequencing (spa typing), coagulase testing, antimicrobial sensitivity testing, and confirmation with Cefitofur resistance and polymerase chain reaction (PCR) for the mecA gene.

**CONTROL**
Control should focus on the careful use of antimicrobials and consistent application of hygiene measures to reduce the spread of infection.\(^{159}\) The reduction of access and exposure to pigs is most important. This means that movement restrictions and farm-level hygiene measures are the only possibilities.

There should be methods for harmonizing the sampling, detecting, and quantifying of MRSA in humans and animals and for detecting MRSA as a contaminant in food and the environment. Professionals connected with animals should also be tested on entry to the hospital. Transfer from animals to humans is difficult to control. Hand washing before and after contact is essential, as is avoiding direct contact with nasal secretions, saliva, and wounds. MRSA organisms can be killed with photodynamics.\(^{160}\)

There is a clear difference between colonization and infection with MRSA.\(^{161}\) Disinfection programs may temporarily reduce MRSA strains for the sow and piglets, but they do not result in a complete removal.\(^{162}\)

These programs are more effective in farrowing units than in finishing units.\(^{163}\) Control programs in abattoirs should involve reduction in carcass contamination.\(^{164}\)

DERMATOPHILOSIS (MYCOTIC DERMATITIS CUTANEOUS STREPTOTRICHOSIS, SENKOBODISEASE OF CATTLE, LUMPY WOOL OF SHEEP)

The disease is commonly called mycotic dermatitis in sheep and cutaneous streptotrichosis in cattle, although other local names exist including Senkobo skin disease in central Africa, Kirchi in Nigeria, and Saria in Malawi. Dermatophilosis is a name common to the disease in all species.

SYNOPSIS

Etiology Dermatophilus congolensis

Epidemiology Organism present in minor carrier lesions on face and feet. Serious disease occurs when body skin is broken by shearing or insect bites, or macerated by prolonged wetting, coupled with management practices that promote transmission. The disease has significant importance in cattle in tropical areas, whereas in high-rainfall temperate climates it occurs mainly in sheep and horses. In tropical areas ticks promote severe infection in cattle by suppression of immune function.

Clinical findings Sheep: hard crusts distributed over backline palpable in fleece. Cattle and horses: nonpruritic crustating dermatitis, initially with paintbrush tufts of hair. In cattle in tropical areas, extensive skin lesions.

Clinical pathology Branching filaments containing cocci in pairs.

Diagnostic confirmation Clinical. Organisms in scrapings or biopsy sections, culture, polymerase chain reaction (PCR).

Treatment Antibiotics. Topical antibacterial in horses.

Control Avoidance of skin trauma and of management practices that promote transmission. Use of topical bactericides to prevent infection of sheared cutcles, and of skin in risk periods. Arcanides in cattle.

ETIOLOGY

D. congolensis is the infectious agent but other damage to the skin from other causes to establish infection. The organism is dimorphic and grows as branched filamentous mycelia containing dormant zoospores that are transformed by moisture to the infective stage of motile isolated coci. There is considerable genetic diversity between isolates. Isolates from the same geographic region are not necessarily closely genetically related, although genotypic variation between isolates is correlated with the host species.

EPIDEMIOLOGY

Occurrence Geographic Occurrence

The disease occurs in all areas of the world but can be epizootic in tropical and subtropical areas of the world, where it can result in considerable economic loss. Surveys of large numbers of cattle in Africa report prevalence rates approaching 15%, with a 100% infection rate in some herds at the peak of seasonal prevalence. In temperate climates the disease is usually sporadic but can still be

of considerable economic importance where predisposing factors pertain. For example, an incidence ranging from 10% to 66% was recorded in nine dairy herds, where shower cooling was the predisposing factor to disease.

High prevalence in sheep flocks occurs in the high- and medium-rainfall areas of Australia. Significant clinical disease has been reported as far north as Canada, the northern United States, and Scotland, and as far south as New Zealand.

Host Occurrence
Disease occurs in cattle, sheep, goats, horses, and donkeys, and occasionally in deer, pigs, camels, and wildlife species. Animals of all ages are susceptible, including sucklings a few weeks old.

Source of Infection
The major source of infection for outbreaks of clinical disease exists with minor active lesions on the face and feet in otherwise healthy carrier animals, and with infection in scabs still carried in the hair and wool from healed lesions.

D. congolensis is not highly invasive and does not normally breach the barriers of healthy skin. These barriers include the stratum corneum, the superficial wax layer produced by the sebaceous glands, and, on the body of sheep, the physical barrier of the wool. On the feet and face, these barriers are easily and commonly broken by abrasive terrain or thorny and spiny forage and feedstuffs.

Dermatophilus may infect these lesions and may be transmitted mechanically by feeding flies to result in minor infection on the face and feet. This subclinical carriage form of the disease is common in most herds and flocks, and the minor lesions are most evident at the junction of the haired and non-haired areas of the nares and of the claws and dewclaws. Minor lesions may also be present in the haired areas of the face and feet and on the scrotum and, in lambs, on the skin along the dorsal midline of the back. They are of no clinical significance to the animal except that they provide a source of more serious infection when other areas of the skin surface are predisposed to infection.

Transmission
Transmission occurs from the carriage lesions by contact from the face of one animal to the fleece or skin of another, and from the feet to the skin during mounting. Infection can be transmitted mechanically by flies and ticks and mediate infection by contaminated dips.

Environmental and Management Risk Factors
Sheep
Prolonged wetting of the fleece is the major risk factor and leads to emulsification of the wax barrier and maceration of the skin surface with disruption of the stratum corneum. A prolonged and heavy rain is sufficient to do this, especially if followed by warm and humid weather that retards drying of the fleece. Increased environmental humidity and temperature, as distinct from wetting of the skin, does not appear to promote the development of lesions. Moisture releases infective zoospores from carriage lesions, and these may be carried mechanically by flies that are attracted to the wet wool. The motile zoospores are aided in their movement to the skin surface by the moisture of the fleece and their positive chemotactic response to carbon dioxide at the skin surface.

A protracted wetting period of the fleece can also occur following dipping, jetting, or spraying of sheep for external parasites when these procedures are conducted at periods greater than 1 to 2 months after shearing; the incidence of mycotic dermatitis in sheep has been shown to increase with the time period between shearing and dipping. The infection onto the fleece comes primarily from the lesions on the face and feet and is promoted by tightly yarding sheep following these procedures.

Shearing cuts also destroy the barriers of the skin, and cuts may become infected mechanically by flies, physically by tight yardsing after shearing, and by mediate infection in dips when sheep are dipped immediately following shearing. The resultant lesions do not spread over the body but provide a significant source of infection for other sheep in the flock when management or climatic circumstances lead to a high degree of flock skin susceptibility. Skin infection can also occur following infection with contagious ecthyma.

Cattle
Temperate Zones
Outbreaks in herds and severe disease in individuals are uncommon but can occur associated with high rainfall, with attack rates of 50%. There is a particular tendency for lesions to occur on the rump and back in females and males, probably as a result of the introduction of infection through minor skin abrasions caused by mounting. Lesions down the flanks of cattle may also result from abrasions and direct infection from the dewclaws during mounting. Other penetrating lesions caused by eartags or biting flies can also result in minor lesions.

The use of periodic showers or continual misting to cool cattle during hot periods is a risk factor for infection in dairy herds. Intercurrent disease and stress are also risk factors, and in infected dairy herds a higher incidence has been observed during the first weeks of parturition in first-calf heifers that also had endometritis or mastitis.

Tropical Zones
Climate is the most important risk factor and in tropical and subtropical regions; the disease has its highest incidence and severity during the humid, high-rainfall season. Animals in which the disease regresses are usually reinfected repeatedly in successive wet seasons. As in sheep, the disease in cattle requires disruption of natural skin barriers. However, prolonged wetting of the skin of cattle does not appear to be a major predisposing factor by itself, and the seasonal occurrence is associated with a concomitant increase in tick and insect infestation. For example, a study in Ethiopia found that although prevalence was higher in cattle in the wet season, in both seasons, infestation with Amblyomma variegatum significantly affected the occurrence of disease, with infested cattle having a risk 7 times higher.

Tick infestation, particularly with A. variegatum, Hyalomma asiaticum, and Boophilus microplus, is strongly associated with the occurrence of extensive lesions of dermatophilosis, which can be minimized by the use of acaricides.

The lesions of dermatophilosis on the body do not occur at the predilection sites for ticks, and it is thought that the importance of tick infestation relates to a tick-produced immune suppression in the host rather than mechanical or biological transmission.

Lesions do occur at predilection sites for biting insects, mainly Stomoxys spp., Lypcerosia spp., Glossina spp., Calliphoridae spp., and mosquitoes. In Africa the disease is often combined with demodicosis to produce Senkobo disease, a more severe and often fatal combination.

Trauma to the skin produced by thorny bushes and the ox-pecker bird (Buphagus africanus africana) can also initiate lesions.

Horses
Biting flies (Stomoxys calcitrans) are thought to act as mechanical vectors of the infection, and the housefly (Musca domestica) can carry infection. Skin damage from trauma or from ectoparasites can predispose for disease, as does wetting from rainfall or from frequent washing.

HOST RISK FACTORS
There are breed differences in susceptibility in cattle and sheep. In Africa, the N'Dama and Muturu cattle breeds and native sheep are resistant, whereas Zebu, White Fulani, Renleto, and European breeds are susceptible. Within-breed differences in susceptibility are also apparent, and genetic markers have been identified in Zebu cattle and Merino sheep. Susceptibility in cattle can be influenced by genetic selection. For example, selection against susceptibility to dermatophilosis, based on a BoLA-DRB3/DOB class II haplotype, reduced the prevalence of disease in
 brahman cattle in martinique from 76% to 2% over 5 years. in the merino, sheep of the strong- or medium-wool strains are more susceptible. open-fleeced sheep and sheep with a low-wax and high-sulfur content in their fleece are more prone to infection.

**PATHOGENESIS**

*D. congolensis* does not live well off the body and in the normal environment, and it is susceptible to the external influences of pH and moisture fluctuations. In the laboratory it can survive for 4 years in otherwise sterile broth culture and for at least 13 years in dry scab material kept at room temperature.

**EXPERIMENTAL DISEASE**

Local lesions, but not with spread to extensive disease, can be readily reproduced in sheep and cattle by removal of the skin wax followed by local challenge. Genetic differences modulate the severity of the lesion that occurs.

**ECONOMIC IMPORTANCE**

**Sheep**

Damage to the fleece causes severe losses, up to 30% loss of value of wool and 40% loss of skin value, and may be so extensive in lambs that spring lambing has to be abandoned. Other losses in sheep are caused by interference with shearing and a very great increase in susceptibility to blow-fly infestation.

**Cattle**

In Africa the disease in cattle causes great losses and many deaths, and the it ranks as one of the four major bacteriologic diseases with equivalent importance to contagious bovine pleuropneumonia and brucellosis. Goats in the same area also suffer a high incidence. Losses are from direct animal loss, decreased work ability of affected oxen, reproductive failure from vulval infection or infection on the limbs of males preventing mounting, death from starvation of calves of dams with udder infection, loss of animal meat and milk production, and downgrading of hides. In temperate climates deaths are uncommon, but cows that fail to respond to treatment and have to be culled are not infrequent. In a study in nine herds in Israel, death or culling rates from this disease ranged from 2% to 17%, and there was an average 23% fall in milk production in affected cattle. Reproductive inefficiency is a common accompaniment in severe cases.

**Zoonotic Implications**

Human infection is reported, such as on the hand of a veterinarian working with infected sheep, but contagion from livestock is rare in spite of ample opportunity.

**PATHOGENESIS**

The natural skin and wool waxes act as effective barriers to infection. Minor trauma, or maceration by prolonged wetting, allows establishment of infection and multiplication of the organism in the epidermis. The formation of the typical pyramid-shaped crusts is caused by repeated cycles of invasion into the epidermis by hyphae, bacterial multiplication in the epidermis, rapid infiltration of neutrophils, and regeneration of the epidermis. The organism in the scab is the source for the repeated and expanding invasion, which occurs until immunity develops and the lesion heals. The scab then separates from the healed lesion but is still held loosely in place by hair or wool fibers. In sheep, the extensive maceration of skin that can occur with prolonged fleece wetting can result in extensive skin lesions under the fleece. In cattle, tick infestation suppresses immune function and promotes the spread of the lesion. Secondary bacterial invasion may occur and gives rise to extensive suppuration and severe toxemia.

**CLINICAL FINDINGS**

**Sheep**

Lesions are commonly not visible in sheep because they are obscured by the fleece, but the crusts can be palpated as hard masses at the surface of the skin (lumpy wool disease) and typically are distributed irregularly over the dorsal midline, with “ribs” spreading laterally and ventrally. The crusts are roughly circular, thick, up to 3 cm, often distinctly pyramidal with a concave base, and often pigmented, and the underlying skin is moist and reddened. The muzzle, face, and ears, and the scrotum of rams, may also be involved. The health of the animal is unaffected unless the lesions are widespread.

Heavy mortalities can occur in very young lambs, where there can be extensive lesions over the body. Many develop cutaneous blow-fly myiasis, and in occasional cases a secondary pneumonia resulting from the organism may cause the death of the animal.

**Cattle**

The early lesion is a pustule, and the hair over the infected site is erect and matted in tufts (paintbrush lesions) with greasy exudate forming crumbly crusts that are hard to remove. These develop into scabs that are greasy and fissures at flexion points, and finally to scabs that are hard, horny, and confluent. The scabs vary in color from cream to brown, are 2 to 5 cm in diameter, and are often in such close apposition that they give the appearance of a mosaic. In the early stages the crusts are very tenacious, and attempts to lift them cause pain. Beneath the crusts there is granulation tissue and some pus. In the later stages, the dermatitis heals and the crusts separate from the skin and are held in place by penetrating hairs, but they are easily removed.

Lesions occur on the neck, body, and back of the udder and may extend over the sides and down the legs and the ventral surface of the body. Commonly they commence along the back from the withers to the rump and extend halfway down the ribcage. In some animals the only site affected is the flexor aspect of the limb joints, the inguinal area, or between the forelimbs.

In young calves, infection commences on the muzzle, probably from contact with the infected udder or because of scalding by milk in bucket-fed calves, and may spread over the head and neck.

**Horses**

Lesions in horses are similar to those in cattle. The hairs are matted together over the lesion, and an exudative dermatitis produces a firm mat of hairs and debris just above the skin surface. If this hair is plucked, the entire structure may lift off, leaving a characteristic oval, slightly bleeding skin area. No pruritus or irritation is apparent, although the sores are tender to the touch.

Infection can appear on the head, beginning at the muzzle and spreading up the face to the eyes, and if sufficiently extensive may be accompanied by laceration and a profuse, mucopurulent nasal discharge. In some horses the lesions are confined to the lower limbs, with a few on the belly. In very bad environmental conditions the lesions may be widespread and cover virtually the whole of the back and sides. The lesions on lower limbs are most common behind the pastern, around the coronet, and on the anterior aspect of the hind cannon bones. If the underlying skin cracks, the horse can become very lame. This variable distribution of lesions may depend on the inciting skin trauma.

**Goats**

Lesions appear first on the lips and muzzle and then spread, possibly by biting, to the feet and scrotum. They may extend to all parts of the body, especially the dorsal midline and inside the thighs. In some cases lesions commence on the external ear. Heavy crust formations may block the ear canal and the external nares.

**CLINICAL PATHOLOGY**

The causative organism may be isolated from scrapings or a biopsy section and is much easier to isolate from an acute case than a chronic one. Polymyxin B sulfate can be used to suppress contaminants. Typical branching organisms with double rows of zoospores can be seen in a stained impression smear made directly from the ventral surface of a thick scab pressed firmly onto a slide. The organism can also be demonstrated by fluorescent antibody. ELISA and counterimmunoelectrophoresis have been used to detect serologic evidence of infection, and a real-time PCR test for rapid detection of *D. congolensis* has been developed in Spain.1
NECROPSY FINDINGS

In animals that die, there is extensive dermatitis, sometimes a secondary pneumonia, and often evidence of intercurrent disease.

Samples for Confirmation of Diagnosis
- **Bacteriology**—affected skin and draining lymph node (CYTO FUNGAL CULT)
- **Histology**—formalin-fixed samples of these tissues (LM)

DIFFERENTIAL DIAGNOSIS

- Ringworm
- Staphylococcal dermatitis/folliculitis
- Scabies
- Pediculosis
- Fleece rot—sheep

Other causes of dermatitis are listed in Tables 16.3 and 16.4.

TREATMENT

Sheep

Bactericidal dips are used but have limited efficacy because topical treatments do not penetrate the scab to the active lesion; they are more appropriate for control.

Antibiotic treatment at high dose for a single treatment is effective in reducing the proportion of active lesions in an affected flock. Antibiotics that are effective include procaine penicillin combined with streptomycin at a dose of 70,000 units/kg and 70 mg/kg, respectively; erythromycin at 10 mg/kg; long-acting tetracycline at 20 mg/kg; and combination of lincomycin and spectinomycin at a dose of 5 mg/kg and 10 mg/kg, respectively; all treatments are given intramuscularly. Treatments appear effective in wet weather. The usual strategy is to treat 8 weeks before shearing so that there is time for the lesions to heal and shearing to occur without interference from active lesions. Sheep may be dipped in a bactericidal dip after shearing, as detailed under “Control.” An alternate approach is to pull affected sheep.

Cattle

With the disease that occurs in temperate areas, tetracycline (5 mg/kg body weight [BW]) repeated weekly as required is recommended, and long-acting tetracycline (20 mg/kg BW) in one injection is reported to give excellent results in cattle. Parenteral procaine penicillin G (22,000 IU/kg IM) daily for 3 days is also reported as efficacious.

With the disease that occurs in tropical areas and associated with tick infestation, there is no completely satisfactory treatment in herds with extensive involvement or those being constantly reinfected or exposed to predisposing causes. In general terms, better results are obtained during dry weather and in dry climates. In tropical Africa, treatments that are reasonably effective elsewhere are of little or no value. Parenteral treatment with antibiotics, as described previously, can be used and should be used in conjunction with acaricides when ticks are present.

Horses

Topical therapy is most commonly used in horses, coupled with removal from whatever is causing prolonged wetness of the skin. Although horses generally respond well, in bad weather even they can be recalcitrant to treatment. Scabs can be removed by grooming under sedation and the lesions treated topically daily with povidone-iodine or chlorhexidine until the lesions heal. Benzoyl peroxide has keratolytic, antibacterial, and follicular flushing properties and is reported to be effective in therapy when applied topically at a concentration of 2.5%.

Severe cases can be treated daily for 3 days with procaine penicillin G at 20,000 units/kg intramuscularly alone or in combination with streptomycin at 10 mg/kg IM.

CONTROL

The principal approach, where possible, is the avoidance of predisposing factors. The disease usually disappears in dry weather. Isolation of infected animals and avoidance of contact by clean animals with infected materials such as grooming tools is desirable. Affected sheep should be shorn and/or dipped last.

Close yarning of sheep or farms that promote face-to-skin contact immediately after shearing or after dipping should be avoided. Insecticidal dips should contain a bactericide. Where dipping immediately after shearing is a risk factor, the severity of infection can be reduced by delaying dipping, for example, from the 1st to the 10th day after shearing, or by dipping in zinc sulfate immediately following shearing with later dipping in an insecticide. Alternatively, pour-on insecticides can be used.

Bactericidal dips will give some protection to sheep. Spraying or dipping of sheep in a 0.5% to 1.0% solution of zinc sulfate immediately after shearing is used to prevent infection of shear cuts. Spraying or dipping sheep in a 1% solution of alum (potassium aluminate) provides protection against infection for up to 70 days, with alum rendering the organism nonmotile, and can be used to provide protection during the rainy season in woolled sheep. Alum strips from the dip, and the dip requires frequent replenishment, with the amount depending on wool length. An alternate treatment is to dust alum along the back of the sheep.

With cattle in tropical areas, **tack control** (see Tick Infestations in this chapter) is most important in control of dermatophilosis. Attempts at prophylaxis by vaccination in both sheep and cattle have been unsuccessful; immunity appears to be isolate-specific.

REFERENCES

SKIN TUBERCULOSIS

Chronic indurative lesions of the skin in cattle, occurring usually on the lower limbs, are called “skin tuberculosis” because they frequently sensitize affected animals to tuberculin.

ETIOLOGY

Acid-fast organisms can often be found in the lesions in small numbers. They have not been identified and are probably not true pathogens. Iatrogenic lesions may be caused by aluminum adsorbed vaccines that produce subcutaneous granulomas, which are colonized by acid-fast bacteria.

EPIDEMIOLOGY

The disease occurs in most countries of the world, particularly where animals are housed and incur minor abrasions and pressure sores. The frequent occurrence of lesions on the lower extremities suggests cutaneous abrasions as the probable portal of entry of the causative organism.

The lesions cause little inconvenience but are unsightly, and affected animals may give a suspicious or positive reaction to the tuberculin test when they are in fact free of tuberculosis. This becomes important when herds and areas are undergoing eradication and attention is focused on any condition that complicates the tuberculin test.

PATHOGENESIS

Tuberculoid granulomas occur at the site of infection, with spread along local lymphatic vessels but without involvement of lymph nodes.

CLINICAL FINDINGS

Small lumps 1 to 2 cm in diameter appear under the skin. The lower limbs are the most common site, particularly the forelimbs, and spread to the thighs and forearms, and even to the shoulder and abdomen, may occur. The lesions may be single or multiple and often occur in chains connected by thin cords of tissue. The nodules are attached to the skin; they may rupture and discharge thick cream-to-yellow pus. Ulcers do not
Diseases

Diseases of the Skin, Eye, Conjunctiva, and External Ear

Chapter 16

Persist. Individual lesions may disappear, but complete recovery to the point of disappearance of all lesions is unlikely if the lesions are large and multiple.

CLINICAL PATHOLOGY

Affected animals may react to the tuberculin test. Bacteriologic examination of smears of pus may reveal the presence of acid-fast bacteria.

NECROPSY FINDINGS

The lesions comprise much fibrous tissue, usually containing foci of pasty or inspissated pus, and are sometimes calcified.

DIFFERENTIAL DIAGNOSIS

In herds with tuberculosis, reactors that have lesions of skin tuberculosis are disposed of in the usual way. In herds free of tuberculosis, a positive reaction to the tuberculin test in animals with skin tuberculosis is usually taken to be nonspecific; the affected animal is retained, provided it is negative on retest.

Bovine farcy (see also "Bovine Farcy")

Ulcereative lymphangitis (see also "Ulcereative Lymphangitis")

TREATMENT AND CONTROL

Treatment and control measures are not usually instituted, although surgical removal may be undertaken for cosmetic reasons.

MYCOBACTERIUM ULCERANS INFECTION (BURULI OR BAIRNSDALE ULCER)

*Mycobacterium ulcerans* causes progressive ulcers in the skin of humans, dogs, cats, alpacas, horses and wildlife.1–5 Pigs can be infected experimentally.6 The disease in humans occurs in at least 30 countries, often as geographic clusters associated with water bodies. Wildlife, such as the common bush-tailed possum (*Trichosurus vulpecula*) and ring-tailed possum (*Pseudocheirus peregrinus*) in southeastern Australia, are proposed as important components of the disease infection cycle, with *M. ulcerans* detected in the feces of 41% of possums in areas in which the disease is endemic and less than 1% in nonendemic areas.7 Clusters of the disease in people are spatially associated with the presence of possums.8 A relationship between wildlife and domestic animal disease has not been investigated or reported. The organism can be detected in a number of species of mosquitoes, although the importance of these species in spread of the infection and causation of disease is unclear.9

Infection by the organism causes extensive and progressive necrosis of the skin and underlying soft tissue, usually of the limbs or extremities. The disease is reported in the thigh of one horse and the withers and fetlock of another,1 and the distal limb and face, respectively, of two alpacas.4 Infection causes both ulcerating and nonulcerating granulomatous lesions in dogs and cats.6 One of two horses affected died as a result of the disease, as did both alpacas.1,4

Diagnosis is by the demonstration of the organisms by Ziehl–Neelsen staining of biopsies of lesions with confirmation by culture or, more conveniently and presumably with greater sensitivity, by PCR detection of *M. ulcerans* genome.1,2,4

Treatment is by surgical excision of the lesion. Therapy with antimycobacterial drugs such as rifampin, clarithromycin, or fluoroquinolones can be considered but is limited because of drug-induced toxicoses, including diarrhea, difficulty in long-term administration, and expense.

There are no accepted control measures. The disease has zoonotic potential, and affected animals and samples should be handled accordingly.

FLEECE ROT IN SHEEP

SYNOPSIS

**ETIOLOGY** Dermatitis associated with growth of chromogenic *Pseudomonas aeruginosa* following prolonged wetting of the skin of sheep.

**Epidemiology** Occurs with high incidence in sheep with susceptible fleece characters in wet seasons. Major risk factor for body flystrike.

**Clinical findings** Dermatitis with fleece coloration over the backline.

**Diagnostic confirmation** Clinical.

**Control** Selection of sheep with resistant fleece characters.

**ETIOLOGY**

Fleece rot develops as an exudative dermatitis with fleece bacteria, including *P. aeruginosa*, and areas of New Zealand. Its occurrence is associated with wet years, and in these circumstances the incidence in affected flocks varies from 40% to 100%.1,2

Environment and Host Risk Factors

Fleece rot occurs in sheep only in wet seasons and when the fleece is predisposed to wetting by its physical characters. Prolonged rainfall, sufficient to wet sheep to the skin for a week, is required for this condition to occur. Young sheep (those < 10 months) are more susceptible than old, and heritable differences in fleece characters affect the susceptibility of individual sheep. These characters are probably related to the ease with which the skin can be wetted.

**Fleece Characteristics**

The degree of “grip” and body skin wrinkling are unimportant as factors affecting susceptibility, but fleece weight, fiber diameter and variability, staple density, and neck wrinkle are positively correlated with susceptibility. These characteristics produce visible differences between fleeces. Resistant sheep have closely packed elliptical wool staples with blocky tips and even crimp. Susceptible fleeces have thin staples of unevenly crimped wool and with a fringe-tipped appearance as a result of the protrusion of thicker wool fibers above the top of the staple. This fringed appearance is visible along the back and sides. Susceptible fleeces are characterized by fleeces with longer, heavier, thicker staples with lower crimp frequency and higher fiber diameter and variability.

Fleeces with a high wax content are less susceptible, probably because of the waterproofing effect of the wax. This view is supported by the observation that disruption of the sebaceous layer on the skin increases its susceptibility to wetting.

Greasy fleece color has been found to be a good predictor of susceptibility to fleece rot in some studies but not others. Wool with a high suint content is highly susceptible.

Experimental Production

The disease can be reproduced experimentally by inoculating *P. aeruginosa* epicutaneously and wetting the fleece.

Economic Importance

Fleece rot causes considerable financial loss because of the depreciation in the value of the damaged fleeces and the increased need for chemical applications to treat or prevent body flystrike, for which it is a major risk factor.

PATHOGENESIS

With prolonged wetting, conditions of high humidity in the fleece microenvironment and the availability of rich nutrients from serous exudates and indigenous suint allow the proliferation of opportunistic skin and fleece bacteria, including *P. aeruginosa*, and
result in dermatitis. The predominant bacterium is usually *P. aeruginosa*, which inhibits the growth of other bacteria, and its pyocyanin produces a green color. Its rapid growth is accompanied by the production of the demecrotoxin phospholipase C, which exacerbates the dermatitis and initiates the inflammatory cascade that draws neutrophils and lymphocytes into the skin.

In the experimental disease there is outpouring of serous exudate and infiltration of leukocytes into dermis, but *P. aeruginosa* is localized as aggregates at the leading front of the seropulent exudate and never penetrates the dermis.

Other discolorations may occur depending on the predominance of a particular chromogenic bacterium, many of which belong to *Pseudomonas* spp. *P. multophilia* can result in yellow–brown coloration, and *P. indigocarpa* results in blue coloration.

The odor produced by the bacteria and the serum protein on the skin surface is very attractive to blow flies, and most body strikes are a result of preexisting fleece-rot lesions. To add a further complication, *P. aeruginosa* also proliferates in the presence of organophosphorous insecticides and facilitates its biodegradation.

Sequencing of 16SrRNA genes to identify bacteria present before and after the onset of disease in an experimental flock at Trangie in Australia identified several new bacteria associated with fleece rot, and the bacterial populations differed between susceptible and resistant sheep. It was concluded that although *P. aeruginosa* may be associated with severe fleece-rot lesions, there may be other bacteria associated with susceptibility or resistance to this condition. Subsequently, investigation of single-nucleotide polymorphisms between susceptible and resistant sheep identified 155 genes that were differentially expressed. Fibulin (FBLN1) and fatty acid binding protein 4 (FAB4) were identified as key factors in resistance to fleece rot. If validated in larger populations, these could enable marker-assisted selection to increase the resistance of Merino sheep to fleece rot.

**CLINICAL FINDINGS**

Lesions occur most commonly over the withers and along the back. In active cases, the wool over the affected part is always saturated, and the tip is more open than over unaffected areas. The wool is leached and dingy and in severe cases can be plucked easily. The skin is inflamed, and serous exudate produces bands of matted and colored fibers across the staple. The coloration of the fibers is commonly green, but may be yellow, yellow–brown, or red–brown and occurs in fibers at skin level or extending the full length of the staple.

The general health of the sheep is unaffected in typical fleece rot, but severe ulcerative dermatitis with mortality associated with *P. aeruginosa* can occur. For example, chronic ulcerative and necrotic dermatitis associated with *P. aeruginosa*, occurring on the tail, udder, and legs of sheep and accompanied by green coloration of the surrounding fleece, was recorded following excessive rain in the Mediterranean climate zone of Israel.

**CLINICAL PATHOLOGY AND NECROPSY FINDINGS**

Autopsy examinations are not carried out, and laboratory examination of the living animal is not usually necessary.

There are differences in the inflammatory response and in peripheral blood lymphocyte subsets between fleece-rot-resistant and susceptible sheep, with several different mechanisms likely to occur in resistant sheep.

**DIAGNOSIS**

Fleece rot resembles mycotic dermatitis in body distribution and predisposing factors, but the typical scab is not present in fleece rot.

**TREATMENT**

Treatment is unlikely to be of value, but some degree of control may be effected by selection of fleece-rot-resistant sheep for use in susceptible localities. In these same localities, shearing before the wet season should facilitate drying of the fleece and lessen susceptibility, although the variable and unpredictable timing of rainfall means that no shearing time will reliably prevent fleece rot. The heritability of resistance to fleece rot has been estimated to be between 0.35 and 0.4; thus, selective breeding programs have been advocated, with genetically selected lines showing increased resistance in high-risk environments.

Considerable effort was invested into the investigation of vaccines against fleece rot in the 1980s and 1990s. These reduced the severity of fleece rot in pen experiments, often by up to 60%, but when the infecting serotype of *P. aeruginosa* differed from the vaccine strain there was little cross protection.

**REFERENCES**

**BOLO DISEASE**

This disease of the fleece of predominantly merino and Dohne merino sheep appears confined to the Eastern Cape province of South Africa and gets its name from the region where it was first described. An unclassified *Corynebacterium* spp. closely resembling *Corynebacterium pseudodiphtheriticum* and *Corynebacterium urealyticum* can be isolated from the skin of affected sheep. This organism is rarely isolated from the skin of sheep with normal fleeces. The disease can be experimentally reproduced by the topical application of the organism onto the intact skin of newly shorn sheep and sheep in 5-month wool, and the organism persists in the produced lesions for at least 169 days.

Bolo disease is a disease of medium- and medium–strong-wool Merino sheep having dense fleeces with a high yolk content. It occurs in sheep on natural grazing. There is no sex predilection, but older and poor-conditioned sheep are more severely affected. It can occur in semiarid climates, and there is no apparent seasonal or climatic influence or influence of external parasites. The attack rate in a flock can be as high as 90%, and the disease has considerable economic impact because as the wool is of inferior quality and low economic value.

Lesions occur most commonly on the sides of neck and the shoulders and are more easily seen in unshorn sheep as well-defined, dark gray to black patches and bands that vary in number and in size (20 mm to 30 cm in diameter) and are sunk below the surface of the tips of the surrounding staple. The underlying skin is red–purple in color, is tender to the touch, and breaks easily. There is a yellow sticky exudate on the surface of the skin and in between the wool fibers, resulting in a stippled staple. On freshly shorn sheep, the affected areas are chalky white.

Histologically there is acanthosis, superficial and follicular hyperkeratosis and hyperpigmentation, and sebaceous gland hypertrophy.

Treatment regimens are not defined, but high-dose parenteral penicillin as used in mycotic dermatitis might be effective.

Bolo disease can be differentiated from fleece rot and mycotic dermatitis by its clinical presentation and the epidemiologic circumstances in which it occurs.

**FURTHER READING**

**STRAWBERRY FOOTROT OF SHEEP (PROLIFERATIVE DERMATITIS)**

Strawberry footrot of sheep is a proliferative dermatitis of the lower limbs of sheep.

**ETIOLOGY**

The causative agent is thought to be *D. congoensis* (*Dermatophilus pedis*).

**EPIDEMIOLOGY**

The disease is recorded in the United Kingdom and occurs extensively in some
parts of Scotland and in Australia. It is not fatal, but severely affected animals do not make normal weight gains. Up to 100% of animals in affected flocks may show the clinical disease.

All ages and breeds appear susceptible, but under natural conditions lambs are more commonly affected. Most outbreaks occur during the summer months, and lesions tend to disappear in cold weather. Although the disease is recorded naturally only in sheep, it can be transmitted experimentally to man, goats, guinea pigs, and rabbits. Complete immunity does not develop after an attack, although sheep recently recovered from contagious ecthyma may show a transient resistance.

The natural method of transmission is unknown, but the frequency of occurrence of lesions at the knee and coronet suggests infection from the ground through cutaneous injuries. Dried crusts containing the causative agent are infective for long periods, and ground contamination by infected animals, or infection from carrier animals, is the probable source of infection.

PATHOGENESIS

Histologically, the lesions are those of a superficial epidermitis similar to that of contagious ecthyma.

CLINICAL FINDINGS

Most cases appear 2 to 4 weeks after sheep have been moved onto affected pasture, but incubation periods of 3 to 4 months have been observed. Small heaped-up scabs appear on the leg from the coronet to the knee or hock. These enlarge to 3 to 5 cm in diameter and become thick and wart-like. The hair is lost, and the lesions may coalesce. Removal of the scabs reveals a bleeding, fleshy mass resembling a fresh strawberry, surrounded by a shallow ulcer. In later stages the ulcer is deep and pus is present. There is no pruritus or lameness unless lesions occur in the interdigital space. Most lesions heal in 5 to 6 weeks, but chronic cases may persist for 6 months.

CLINICAL PATHOLOGY

Swabs and scrapings should be examined for the causative organism.

TREATMENT

There is little information on treatment. Antibiotics as used in dermatophilosis should be effective. In an unusual outbreak of lameness affecting 40% of a flock, with lesions resembling strawberry footrot but from which no organisms were isolated, the response to topical antibiotic and preparations was poor, although lesions did become less painful after bathing affected areas in a solution of lincomycin/spectinomycin. Systemic treatment with tilmicosin and long-acting amoxicillin did assist healing.

CONTROL

In the light of present knowledge, isolation of infected sheep and the resting of infected fields are the only measures that can be recommended.

CONTAGIOUS ACNE OF HORSES (CANADIAN HORSEPOX, CONTAGIOUS PUSTULAR DERMATITIS)

Contagious acne of horses is characterized by the development of pustules, particularly where the skin comes in contact with the harness.

ETOLOGY

Corynebacterium pseudotuberculosis is the specific cause of this disease.

EPIDEMIOLOGY

The disease is spread from animal to animal by means of contaminated grooming utensils or harnesses. An existing seborrhea or folliculitis as a result of blockage of sebaceous gland ducts by pressure from the harness probably predisposes to infection. Inefficient grooming may also be a contributing cause.

Contagious acne is of limited occurrence and causes temporary inconvenience when affected horses are unable to work.

PATHOGENESIS

Infection of the hair follicle leads to local suppuration and the formation of pustules, which rupture and contaminate surrounding skin areas. Occasional lesions penetrate deeply and develop into indolent ulcers.

CLINICAL FINDINGS

The skin lesions usually develop in groups in areas that come into contact with the harness. The lesions take the form of papules that deepen and develop into pustules varying in diameter from 1 to 2.5 cm. There is no pruritus, but the lesions may be painful to touch. Rupture of the pustules leads to crust formation over an accumulation of greenish-tinged pus. Healing of lesions occurs in about 1 week, but the disease may persist for 4 or more weeks if successive crops of lesions develop.

CLINICAL PATHOLOGY

Swabs of the lesions can be taken to determine the presence of C. pseudotuberculosis.

DIFFERENTIAL DIAGNOSIS

Ringworm
Staphylococcal pyoderma
Nodular necrobiosis
Diagnostic confirmation
Isolation of C. pseudotuberculosis from lesions

TREATMENT

Affected animals should be rested until all lesions are healed. Frequent washing with a mild skin disinfectant solution followed by the application of antibacterial ointments to the lesions should facilitate healing and prevent the development of further lesions. Parenteral administration of antibiotics may be advisable in severe cases.

CONTROL

Infected horses should be rigidly isolated, and all grooming equipment, harnesses, and blankets must be disinfected. Grooming tools must be disinfected before each use. Vaccination is not likely to be effective because of the poor antigenicity of the organism.

EXUDATIVE EPIDERMITIS (GREASY PIG DISEASE)

ETOLOGY

The condition of exudative dermatitis (marmite disease) is similar to staphylococcal scalded skin syndrome in humans associated with S. aureus. It is a skin condition of pigs of all ages. One human case of S. hyicus septicemia has been recorded.

S. hyicus is the cause of exudative epidermitis (EE) in suckling and weaned piglets. It also causes several other diseases sporadically in different animal species, bacteriuria in pigs, polyarthritis in pigs, abortion in pigs, flank biting and necrotic ear lesions, and pneumonia. It is a normal inhabitant of the skin of adults. Virulence is associated with toxins.

In other species it has been associated with skin infections in horses, donkeys, and cattle; subclinical mastitis in cows; and osteomyelitis in heifers.

A second species, Staphylococcus chromogenes, is part of the normal skin flora of pigs, cattle, and poultry. It had been considered nonpathogenic until EE was associated with it in 2005. These strains produced exfoliative
toxin type B (ExLB), which was identified by PCR. A third species, Staphylococcus sciuri, has also caused EE.2

## SYNOPSIS

### Etiology

Staphylococcus hyicus of at least six serotypes and many phase types.

### Epidemiology

Affects suckling and weanling piglets under 6 weeks of age; peak incidence under 1 week of age. Morbidity 20% to 100%; case fatality 50% to 75%. Organism carried by sow. Introduced by carriers.

### Signs

Marked cutaneous erythema and pain, dehydration, excessive greasy exudate; peracute cases die; less severe cases may survive. May cause ear necrosis syndrome.

### Clinical pathology

Bacterial culture of skin.

### Necropsy findings

Exudative epidermitis; degenerative changes in kidney.

### Diagnostic confirmation

Culture of organism.

### Differential diagnosis

See Table 16-2.

### Treatment

Penicillin parenterally.

### Control

Sanitation and hygiene of pens. In outbreaks, isolate affected piglets and sows.

## EPIDEMIOLOGY

### Occurrence

The disease occurs in all pig-producing countries. Most cases of exudative epidermitis occur in suckling and weanling piglets under 6 weeks of age, with a peak incidence in piglets under 1 week. Occasionally groups of pigs up to 3 months of age may be affected. Within litters the incidence is high; often all piglets are affected. The morbidity will vary from 20% to 100% and the case fatality rate from 50% to 75%. The organism has been isolated from the joint fluid of lame pigs affected with arthritis.1 In 28% and 26% of studies of cases of exudative epidermitis, no cases of toxigenic S. hyicus could be detected. In a recent study of 314 cases in Denmark, it was shown that 20% had exfoliatum toxin A, 33% had B, 18% had C, and 22% had D in 60% of cases of EE investigated.

### Method of Transmission

The source of the organism is unknown, but the gilt or sow is probably an inapparent carrier. It can be isolated from the skin of healthy in-contact piglets and healthy sows. It can be frequently isolated from the vagina of prepubertal gilts, and the majority of the litters from the same gilt may be colonized by the organism within 24 hours after farrowing. The maternal strains of S. hyicus persisted on the skin of the offspring piglets for the first 3 weeks of the piglets’ lives—the critical period for outbreaks of exudative epidermitis. The organism has also been isolated from the atmosphere of buildings housing affected pigs. Bacteriophage typing of S. hyicus subspp. hyicus isolated from pigs with or without exudative epidermitis revealed two or more phage patterns in the isolates from each pig with the disease and a single-phage pattern in isolates from healthy pigs. It may also spread by aerosol.

### Pathogenesis

S. hyicus has cytotoxic activity for porcine keratinocyte cells in culture, particularly the cells of the stratum granulosum. At least six toxins have been found. There is also a virulence factor that helps resist phagocytosis by binding IgG.6 The organism also produces a coagulase, streptokinase lipase, and has a fibronectin-like substance that aids attachment to skin cells.

The exfoliative toxins are actually epidermolysins that are active against desmoglein-1, which is a desmosomal cadherin-like molecule involved in cell-to-cell adhesion. The ExLs can cause blister formation in the porcine skin by digesting porcine desmoglein-1 in a similar way to exfoliative toxins of S. aureus. The earliest lesion is a subcorneal pustular dermatitis involving the interfollicular epidermis. Exfoliation follows with sebaceous exudation and formation of a crust. In the well-developed case there is a thick surface crust composed of orthokeratotic and parakeratotic hyperkeratosis and neutrophilic microabscesses with numerous colonies of gram-positive cocci.

Although the principal lesion is an inflammatory–exudative reaction in the corium and upper layers of the epidermis, the disease is probably a systemic rather than a local one. Experimental infection of gnotobiotic pigs leads to dermatitis of the snout and ears, then the medial aspect of the thighs, the abdominal wall, and the coronets. The lesions can be produced experimentally by using crude extracellular products and a partially purified exfoliative toxin.

### CLINICAL FINDINGS

The morbidity varies from 10% to 100% and the mortality from 5% to 90%, with an average of 25%. It is usually self-limiting, and as immunity rises, it may well disappear.

In the peracute form, which occurs most commonly in piglets only a few days of age, there is a sudden onset of marked cutaneous erythema, with severe pain on palpation, evidenced by squealing. Anorexia, severe dehydration, and weakness are present, and death occurs in 24 to 48 hours. The entire skin coat appears wrinkled and reddened and is covered with a greasy, gray–brown exudate that accumulates in thick clumps around the eyes, behind the ears, and over the abdominal wall. In the less acute form, seen in older pigs 3 to 10 weeks of age, the greasy exudate becomes thickened and brown and peels off in scabs, leaving a deep-pink-colored to normal skin surface. There is no irritation or pruritus. In the subacute form, the exudate dries into brown scales that are most prominent on the face, around the eyes, and behind the ears. In a small percentage of pigs, the chronic form occurs and the course is much

</tbody>
</table>
longer; there is thickening with wrinkling of the skin and thick scabs that crack along flexion lines, forming deep fissures. Most peracute cases die, whereas piglets with the less severe forms will survive if treated. Some pigs are affected with ulcerative glossitis and stomatitis.

In older pigs lesions may be very limited. Sometimes just the ears are affected. Abortion in a sow has been attributed to the organism. In some cases pigs are dehydrated and emaciated. Surface lymph nodes may be enlarged or edematous. The condition is much more common when there are the immunosuppressive disorders (Porcine reproductive and respiratory syndrome virus, Porcine circovirus 2, Swine Influenza Virus).

**CLINICAL PATHOLOGY**

Bacterial examination of skin swabs may reveal the presence of *S. hyicus*. A phage typing system can be used to determine the presence of virulent strains and to distinguish them from less virulent strains.

**NECROPSY FINDINGS**

 Necropsy of these dehydrated, unthrifted piglets often reveals a white precipitate in the renal papillae and pelvis. Occasionally this cellular debris causes ureteral blockage. Some piglets also have a mild ulcerative glossitis and stomatitis. Microscopically, there is separation of the cells of the epidermis in the upper stratum spinosum, exfoliation of the skin, erythema, and serous exudation. The crusting dermatitis features a superficial folliculitis and a hyperkeratotic perivascular dermatitis with intracorneal pustules and prominent bacterial colonies. Degenerative changes are visible in the renal tubular epithelium.

**DIAGNOSIS**

Diagnosis is usually made on the basis of clinical signs and lesions.

Samples for confirmation of diagnosis include the following:
- Bacteriology—samples of acute skin lesions for culture are best if the skin underneath the crusts is sampled or the local lymph nodes. The organism forms 3- to 4-mm white, nonhemolytic colonies on blood agar. It is catalase- andmannitol-negative but hyaluronidase-positive. Selective media can be used (potassium thiocyanate),
- **Histology**—formalin-fixed skin (multiple sites), kidney (LM)
- A PCR is available but requires a pure culture and large numbers of organisms to be successful. An ELISA has been developed for the toxins.7

**DIFFERENTIAL DIAGNOSIS**

Exudative epidermitis may resemble several skin diseases of pigs of all age groups (Table 16-2). However, in exudative epidermitis there is no pruritus or fever. In mange there is pruritus, and the lesions can be scraped. Ringworm can be cultured or skin scrapings made for microscopy. Pityriasis rosea is erythematous and self-limiting. Zinc deficiency in 2- to 4-month-old pigs is particularly found in Landrace, and the lesions are dry. Swinepox is usually local and rarely fatal. Careful gross examination of the lesions, particularly their distribution, the state of the hair shaft, the character of the exudate, and the presence or absence of pruritus, must be considered, along with skin scrapings and biopsies.

**TREATMENT**

In severely affected animals, injection is best followed by water and feed medication. Experimentally infected piglets respond favorably to a topical application of cloxacillin 10,000 IU/g of lanolin base and 1% hydrocortisone combined with parental cloxacillin. Treatment must be administered as soon as the lesions are visible. Procaine penicillin G at a dose of 20,000 IU/kg BW intramuscularly daily for 3 days is also recommended. The antimicrobial sensitivities determined in one field investigation revealed that all isolates were sensitive to novobiocin, neomycin, and cloxacillin. Novobiocin may be the antimicrobial of choice because *staphylococci* are universally sensitive to this antibiotic. However, there is no available information on the efficacy of antimicrobials for naturally occurring cases of exudative epidermitis. A study has suggested that lincomycin, amoxicillin, and cefalotin (off-label use) seem to work well in the United Kingdom. Erythromycin, sulfathiazole, and trimethoprim may be the most useful drugs, whereas penicillin and tetracyclines may not be very useful. Resistance to penicillin, erythromycin, streptomycin, sulphonamides, and tetracycline is fairly common. There is, however, no correlation between genes and resistance patterns.2 Naturally occurring cases in piglets under 10 days of age respond poorly, whereas older pigs recover with a skin wash using a suitable disinfectant soap. The most successful treatment is antibiotics and skin washing for a period of at least 5 to 7 days. It is also essential to make sure that there is sufficient dietary provision of zinc, biotin, fat, selenium, and vitamin E in the diet. Because there is dehydration, electrolyte therapy may help.

**CONTROL**

Improved hygiene, lower humidity, and dimmed lighting all help, as will control of concurrent infectious disease. Teeth clipping also reduces skin damage. Soft bedding also reduces skin damage (e.g., chopped straw is better than straw).

The infected accommodation should be cleaned, disinfected, and left vacant before another farrowing sow is placed in the pen. Strict isolation of the affected piglets and their dam is necessary to prevent spread throughout the herd. Dead piglets should be removed promptly from the premises, and in-contact sows should be washed with a suitable disinfectant soap. Maternal antibodies will protect piglets in the first few weeks of life. Prophylactic medication in feed or water has also helped.

Autogenous vaccines have been used, with varying degrees of success. It is important to use a strain that produces the exfoliative toxin, so the recent development of PCRs that identify the genes for toxin development will ensure that the right isolate is used for the autogenous vaccine. It will also facilitate the development of a commercial vaccine.

**REFERENCES**

**ULCERATIVE DERMATITIS (GRANULOMATOUS DERMATITIS) OF PIGS**

Ulcereative granuloma is an infectious disease of pigs originally associated with the spirochete *Borrelia suilla* (formerly *B. suis*) and more recently *T. pedis*. In some cases it has become more common where there is PCV2 infection. It is characterized by the development of chronic ulcers of the skin and subcutaneous tissues. It can be confused with necrotic ear syndrome and, more importantly, with swine vesicular disease when there are granulating lesions at the coronary groove.

For sows, it occurs most commonly under conditions of poor hygiene. Lesions occur on the central abdomen of sows and on the mammary glands. The lesions expand, often to 20 to 30 cm in diameter, on the belly of the sow. They are usually single or in small numbers. In adult animals there is considerable inconvenience if the lesions are permitted to develop. Necrotic ulcers on the udders of sows may continue to develop and extend deeper into areas with fistulae, and sloughing may result.

The faces of sucking piglets are affected, suggesting infection of cutaneous or mucosal
Diseases of skin wounds should reduce the incidence times of routine treatments, and disinfection lesion is reported to give good results. of sodium arsenite into the substance of the granulomas surgically has also been tried. Also been recommended. Removal of large amide, arsenic trioxide, or tartar emetic has more chronic cases. Dusting with sulphanilamide, or viewing in histologic sections. A course of potassium iodide given orally (1 mL of a 5% solution for some neoplastic diseases. Papillomaviruses appear to infect all groups of amniotes, having been isolated from 54 species, including mammals, birds, and reptiles. Study of this group of viruses is historically important in the context of demon- stration of the possibility of a viral etiology for some neoplastic diseases. Diseases associated with infection by papillomaviruses range from nonneoplastic lesions on epithelial surfaces (skin, urogenital tract, gastrointestinal tract) through to neoplasms, including in humans (human papillomavirus and cervical cancer). Cutaneous warts in cattle, horses, sheep, and goats are benign tumors induced by host-specific papilloma- viruses. These infect epithelial cells, causing hyperproliferative lesions that are benign and self-limiting and that, in most cases, spontaneously regress. The virus is also associated with neoplastic diseases, including bladder cancer in cattle ingesting bracken fern, carcinoma of the upper alimentary tract of cattle (usually associated with ingestion of bracken fern), and squamous-cell carcinoma of the penis and prepuce in horses. Papillo- maviruses are usually quite host specific, with the exception of some bovine papillo- maviruses, and require close contact for spread of infection.

**VIROLOGY**

Papillomaviruses (PVs) are members of the Papillomaviridae family, which have a characteristic circular double-stranded DNA genome of around eight kilobase pairs (kbp) that usually contains at least six relatively conserved open reading frames (ORFs) in an early (E1, E2, E6, E7) and a late (L1, L2) region. Papillomaviruses are characterized genetically by the L1 ORF. To date, at least 12 nonhuman papillomaviruses have been identified, and there is the anticipation that more will be detected. It appears that each species carries a suite of papillomaviruses— for example, 13 bovine papillomavirus (BPV) types have been identified in cattle (BPV-1 through BPV-13), 15 canine papillomavirus (CPV) types in dogs (CPV-1 through CPV-15), and 7 equine caballus papillomavirus (EcPV) types in horses (EcPV-1 through EcPV-7). The feline sarcoi-d-associated virus has been proposed as BPV-14; it can infect cattle but has not been demonstrated in horses.

Unusually, horses are also infected by BPV-1 and/or BPV-2, and possibly BPV-13, which are associated with development of sarcomas (see “Sarcoids” for further discussion). Papillomaviruses have been isolated from camels, goats, deer, sheep, and pigs, usually from papillomas or similar epithelial lesions. BPV-1 and BPV-2 are associated with papillomas in yaks and sarcoiids in zebra, giraffes, and sable antelope. New papillomaviruses continue to be identified.

Cattle types show some site predilection or site specificity, as exemplified by the following partial listing:

- **BPV-1**—frond fibropapillomas of teat and skin and penile fibropapilloma
- **BPV-1 and BPV-2**—fibropapilloma of the skin of the anteroventral part of the body, including the forehead, neck, and back; the common cutaneous wart
- **BPV-2**—cauliflower-like fibropapillomas of the anogenital and ventral abdominal skin
- **BPV-2**—associated with bladder cancer in cattle in association with the ingestion of bracken fern (Pteridium spp.) (see “Enzootic Hematuria”)
- **BPV-3**—cutaneous papilloma
- **BPV-4**—papilloma of the esophagus, esophageal groove, forestomach, and small intestine; capable of becoming malignant, particularly in animals fed bracken fern; has site specificity to the upper alimentary tract
• BPV-5, and to a lesser extent BPV-1 and BPV-2, in fibropapilloma/papilloma of the mouth, esophagus, rumen, and reticulum of cattle and water buffalo.  
• BPV-5—rare grain fibropapilloma on the udder; has also been demonstrated in cutaneous skin warts  
• BPV-6—frond epithelial papillomas of the bovine udder and teats  
• BPV-7, BPV-9, and BPV-10—lesions of the teats and udder  
• BPV-10—lingual papilloma  
• BPV-12—associated with papillomas

Although a single BPV type is detected in an individual papilloma, a single animal can have papillomas at different sites associated with different BPV types. Other papilloma of cattle that have regional distribution and may have separate antigenic identity are as follows:

• Oral papillomas, mostly in adult cattle and apparently reaching a high incidence, up to 16% in some areas; these are probably BPV-4
• Papilloma of the larynx in steers
• Papillomavirus has been observed in squamous-cell carcinoma of bovine eyes, although its etiologic role is unclear. Other skin lesions in which papillomavirus plays an etiologic role are:
  • Equine sarcoma, which is associated with BPV-1 and BPV-2, and possibly BPV-13 (see “Sarcoïd,” in this chapter)
  • Squamous-cell carcinoma of sheep (likely OA-PV-3, although this can be isolated from the skin of healthy sheep)
  • Epithelial tumors in goats (although the causal relationship is not clear)
  • Cauliflower-like tumor of the external nares in a chamäon

Equids
Papillomas, aural plaques, and squamous-cell carcinoma in horses are associated with infection by one of the seven equine papillomaviruses. Cutaneous papilloma, including of the penis, and aural or genital plaques are associated with infection by EcPV-1 through EcPV-6. EcPV-7 was isolated from a penile mass that was not histologically classified. Penile papillomas are associated with infection by EcPV-2. EcPV-2 DNA was detected in abnormal tissue in 15 of 16 cases of penile squamous-cell carcinoma, 8 of 8 cases of penile intraepithelial neoplasia, 4 of 4 cases of penile papilloma, and 1 of 2 lymph nodes containing metastatic tumor cells. EcPV-2 DNA was detected in 4 of 39 of penile swabs of healthy horses and in 0 of 20 vulvovaginal swabs. Coinfection by one EcPV appears to be common. Infection by equine papillomavirus EcPV-2, as demonstrated by detection of EcPV-2 DNA in lesions, is associated with squamous-cell carcinoma of the genitalia of horses, being transcriptionally active in tumor but not semen or swabs of healthy horses, and detected in 91 of 103 tissue samples of horses with penile or preputial carcinoma and in 1 of 12 samples from horses free of the disease. There is no evidence to date that EcPV-3 is associated with carcinoma of the penis or prepuce. Papillomavirus DNA is not detected in pericellular squamous-cell carcinoma of horses. Sarcoïds in equids are discussed under that topic.

Pigs
Papillomavirus specific to pigs has been isolated from skin of healthy pigs, but has not been associated with disease.

EPIDEMIOLOGY

Occurrence
Papillomatosis has an international occurrence in all animal species, and sarcomas and urogenital tumors occur in almost all populations of horses. There are few studies of the serorevelation of papillomaviruses in healthy animals. Five of 50 horses without evidence of skin disease or urogenital tumors in Switzerland had EcPV-2-specific DNA amplified but not EcPV-2-specific antibodies detected, 14 of 50 horses had antibodies against EcPV-2 but no DNA detected, and both antibodies and viral DNA were detected in 4 of 50 horses. Neither specific antibodies nor viral DNA were found in 27 of 50 horses (54%). BPV-1 or BPV-2 infection is common in horses and cattle, being detectable by PCR and/or reverse transcription PCR (RT-PCR) in 14 of 70 blood samples (20%) and in 11 of 31 semen samples (35%) from healthy horses; and in 8/12 blood samples of healthy cattle and in 8/9 samples from cattle with papillomatosis. Six of 8 papilloma-free cattle that were positive for BPV also had evidence of expression of BPV in blood.

Papillomaviruses were detected in 28/45 of samples of horses with aural plaques, of which 4/45 were solely EcPV-3 and 17/45 were solely EcPV-4, with 7/45 being coinfected. Viral DNA was not detected in 17/45 of samples. Neither EcPV-3 nor EcPV-4 was detected in samples from 10 horses that did not have aural skin lesions. Similar results demonstrating presence of papillomavirus antigen or EcPV DNA in papillomas, aural plaques, and sarcomas supports the etiologic association between the virus and these diseases.

Origin of Infection and Transmission
The method of spread is by direct contact with infected animals, with infection gaining entry through cutaneous abrasions. Viruses can also persist on inanimate objects in livestock buildings and infect animals rubbing against them. BPV-1 DNA is present in flies (Musca domestica, Fannia carnicularis, and Stomoxys calcitrans) trapped in stables of donkeys with sarcoïds, suggesting the possibility that flies, and especially biting flies (S. calcitrans), are potential vectors. The presence of BPV-1 and BPV-2 in blood of both horses and cattle raises the possibility of spread by biting flies independent of them feeding on actual lesions.

The means of transmission of the virus causing penile and preputial papillomas and squamous-cell carcinoma is unclear. Veneereal transmission is possible, but lesions occur in animals that are not and have not been sexually active (e.g., geldings). Crops of warts sometimes occur around eartags, at branding sites, or along scratches made by barbed wire, and they can be spread by tattooing implements, by dehorning shears, and by procedures such as tuberculin testing.

An extensive outbreak of periorbital papillomatosis in cattle is recorded in association with a heavy periorbital infestation with Haematopinus quadripertusus.

Animal Risk Factors
All species may be affected by papillomas or fibropapilloma, but it is most commonly reported in cattle and horses. With cattle, usually several animals in an age group are affected. Alimentary papillomas occur in up to 20% of cattle ingesting bracken fern, but in less than 4% of other cattle.

Outbreaks have been recorded in sheep and goats, but the disease is uncommon in sheep. It is also uncommon in pigs, usually affecting the genitalia.

Papillomavirus infection is widespread in nondomestic species, including birds and reptiles, and is associated with disease in many of these species (see previous discussion).

Age
Cutaneous papillomas of the head and neck occur predominantly in young animals, the lack of susceptibility of adults to natural infection being ascribed to immunity acquired by apparent or inapparent infection when young. The occurrence of cutaneous warts and their severity can be influenced by factors that induce immunosuppression, and latent infection has converted to clinical disease with the administration of immuno-suppressive agents. Congenital infection is recorded in the foal and calf, but it is rare.

Alimentary papillomas in cattle, teat papillomas in cattle, and papillomas on the mammary glands of goats occur, or persist, at all production ages. Squamous-cell carcinoma of the penis or prepuce occurs mostly in older horses (mean
Experimental Production
The supernatant from a suspension of wart tissue, injected intradermally (ID) or applied to skin scarifications, is an effective means of experimental production of the disease. Lesions are restricted to the site of inoculation. Cutaneous and oral papillomas have been transmitted in cattle, and cutaneous papillomas have been transmitted in sheep and horses. The incubation period after experimental inoculation in cattle is 3 to 8 weeks but is usually somewhat longer after natural exposure.

Economic Importance
Cutaneous warts are quite common in young cattle, especially when they are housed, but ordinarily they cause little harm and regress spontaneously. In purebred animals they may interfere with sales and shows because of their unsightly appearance. Animals with extensive lesions may lose condition, and secondary bacterial invasion of traumatized warts can occur. Warts on the teats of dairy cows often cause interference with milking. In horses, the lesions are usually small and cause little inconvenience, but they are esthetically unattractive.

Urogenital lesions in equids, predominantly penile and preputial papillomas, can progress to squamous-cell carcinoma, which carries a poor prognosis unless treated early in the disease.  

PATHOGENESIS
The virus infects the basal keratinocytes, replicating its genome in the differentiating spinous and granular layers and causing the excessive growth that is characteristic of wart formation. Expression of the late structural proteins of the virus is limited to the differentiated cells of the squamous layer where the new virus particles are encapsulated and shed into the environment as the cells die. The tumor contains epithelial and connective tissues and can be a papilloma or a fibropapilloma, depending on the relative proportions of epithelial and connective tissue present; papillomas contain little connective tissue, and fibropapillomas are mostly fibrous tissue, with very little epithelial tissue. Papillomas are the result of basal-cell hyperplasia without viral antigen production. Fibropapillomas are uncommon in horses but are the common lesion in cattle, sheep, and wild ruminants. Latent infection in the skin and lymphocytes has been demonstrated in cattle.

CLINICAL FINDINGS
Warts are solid outgrowths of epidermis that are sessile or pedunculated. Other papillomavirus-associated diseases include penile or preputial lesions in horses, alimentary lesions in ruminants, enzootic hematuria in cattle ingesting bracken fern, and squamous-cell carcinoma of the urogenital or alimentary tracts.

Cattle
In cattle, warts occur on almost any part of the body, but when numerous animals in a group are affected it is common to find them all affected in the same part of the body. The most common papillomas occur in the skin of cattle under 2 years of age, most commonly on the head (Fig. 16-2), especially around the eyes, and on the neck and shoulders (Fig. 16-3), but they may spread to other parts of the body. They vary in size from 1 cm upward, and a dry, horny, cauliflower-like appearance is characteristic. In most animals they regress spontaneously, but the warts may persist for 5 to 6 months, and in some cases for as long as 36 months, with serious loss of body condition.

Warts on the teats manifest with different forms depending on the papillomavirus type and may show an increasing frequency with age. The frond forms have filiform projections on them and appear to have been drawn out into an elongated shape of about 1 cm in length by milking machine action. If sharp traction is used, they can often be pulled out by the roots.

The second form is the flat, round type, which is usually multiple, always sessile, and up to 2 cm in diameter. The third form has an elongated structure appearing like a rice grain. Teat warts may regress during the dry period and recur with the next lactation.

Perianal warts are esthetically unattractive, but they do not appear to reduce activity or productivity. Genital warts on the vulva and penis make mating impracticable because the lesions are of large size, are friable, and bleed easily. They commonly become infected and flyblown. They occur on the shaft or on the glans of the penis in young bulls, may be single or multiple, are pedunculated, and frequently regress spontaneously.

Alimentary tract papillomas can occur anywhere from the mouth to the rumen. They often appear as lines of warts, suggesting a predisposing effect of trauma as a result of ingestion of roughage. Papillomas occur on the lateral and dorsal aspects of the tongue, soft palate, oropharynx, esophagus, esophageal groove, and rumen. Papillomas occurring in the esophageal groove and in the reticulum are a cause of chronic ruminal tympany. Papillomas also can progress to squamous-cell carcinoma in cattle, with an inevitable fatal outcome.

Less common manifestations of papillomatosis in cattle include lesions in the urinary bladder, which cause no clinical signs but may predispose to enzootic hematuria. BPV-4 papillomas in the upper alimentary tract of cattle being fed bracken fern are the focus for transformation to squamous-cell carcinomas. Cattle fed bracken fern are immunosuppressed, which promotes the persistence and spread of the papillomavirus, and mutagens in bracken fern cause neoplastic transformation of papilloma cells.
Goats
Papillomas most commonly occur on the face and ears but may occur on the skin generally, especially on unpigmented skin. Most completely regress, others regress and recur, and occasional lesions progress to carcinomas. Papillomas that occur on the teats are persistent and may spread through the herd.

Horses
Warts are confined to the lower face, the muzzle, nose, and lips, and are usually sessile and quite small, rarely exceeding 1 cm in diameter. Papillomas also occur on the penis and prepuce of both geldings and stallions, and much less commonly on the vulva. All ages can be affected. Spontaneous recovery of papillomas on the head is unusual, but the warts may persist for 5 to 6 months.

Aural plaques in horses are well-delineated lesions that affect the concave aspect of the pinna with a flat surface of whitish keratinous crust covering a shiny and erythematous skin surface. Lesions are single or multiple and coalescing and, in some cases, can cover almost the entire surface of one or both pinnae (Fig. 16-4). The lesions are usually not pruritic, but some horses with aural plaques resist bridling or handling of the ears. A common concern is cosmetic in show horses.

Squamous-cell carcinoma of the penis and prepuce is usually evident as ulcerations or mass lesions and can be complicated
by secondary bacterial infection. Approximately 40% of affected horses have purulent or blood-stained preputial discharge. Preputial edema or the inability to prolapse the penis occurs in approximately 10% of horses. Lesions are most commonly (~80%) located on the glans of the penis and can have papillomas neighboring the neoplastic tumor. Metastasis to inguinal lymph nodes is common as the disease progresses and is more likely in horses with poorly differentiated tumor.

Diseases

- papillomas: dermal component tends to be solid and composed of scant dermal tissue, whereas in fibroplasias and sarcoids, the epidermis is hyperplastic.
- True papillomas: different types depending on the level of differentiation of the tumor (log rank P < 0.001), with a greater proportion of poorly differentiated tumors dying of the disease (papilloma, 8.3%; G1, 26.1%; G2, 26.3%; G3, 63.3%; where G1 = well differentiated, G2 = moderately differentiated, and G3 = poorly differentiated) (Fig. 16-5).

**CLINICAL PATHOLOGY**

There are no specific changes in the hemogram or blood chemistry of affected cattle. As noted previously, papillomavirus can be detected in blood and semen of healthy and affected animals, varying with the species of animal and papillomavirus.

Biopsy of a lesion can be used to differentiate papillomas from squamous-cell carcinomas. Biopsy of classic “warts” is unnecessary. However, it may be advisable when large growths are found on horses to determine whether the lesion is a verrucose form of sarcoid. Microscopically, true papillomas consist of a hyperplastic epidermis with scant dermal tissue, whereas in fibroplasias and sarcoids, the dermal component tends to predominate. The need to identify the specific virus in a crop of warts creates a requirement for serologic and histologic examinations.

Detection of viral DNA is achieved by RT-PCR or PCR, and serologic tests are available to determine exposure to some papillomaviruses.

**DIFFERENTIAL DIAGNOSIS**

Clinically, there is little difficulty in making a diagnosis of dermal papillomatosis, with the possible exception of atypical papillomas of the penis, probably associated with an unidentified type of the papillomavirus. These lesions are characterized by an absence of dermal fibroplasia and are true papillomas rather than fibropapillomas. All ages of animals can be affected, and the lesions persist for long periods. They are characteristically discrete, low, flat, and circular, and they often coalesce to form large masses. They do not protrude like regular warts, and the external fronds are much finer and more delicate.

**Horses:**
- Sarcomas
- Melanoma

**TREATMENT**

Warts can be removed by surgery or cryosurgery. Crushing of a proportion of small warts, or the surgical removal of a few warts, has been advocated as a method of hastening regression, but the tendency for spontaneous recovery makes assessment of the results of these treatments very difficult. Partial resection of a wart(s) in a horse does not always promote resolution of the residue. Surgical removal can be followed by vaccination with an autogenous vaccine, although the efficacy of this approach is unclear. There is anecdotal concern that surgical intervention, and even vaccination, in the early stages of wart development may increase the size of residual warts and prolong the course of the disease.

Aural plaques in horses can be treated by application of imiquimod, an immunomodulator, and antiviral agents, as 5% cream applied three times a week, every other week, for 6 weeks to 8 months. Crusts were removed before each application of the cream and required sedation in most horses. Complete resolution of lesions was noted in all horses at the cessation of treatment, and the long-term resolution rate was 88%. Imiquimod is used for treatment of penile papillomas and squamous-cell carcinoma in humans, but its use in horses for this purpose is not reported. Imiquimod is used for treatment of sarcomas in horses.

**Vaccination**

For cattle, autogenous vaccines prepared from wart tissues of the affected animal are effective in many cases. Commercially available vaccines are available for cattle but may be less efficacious; an autogenous vaccine prepared for a specific problem has the advantage of including the local virus types. The vaccine is prepared from homogenized wart tissue that is filtered and inactivated with formalin. Because of the different BPV types, care is required in the selection of the tissues. In general terms they can be selected based on tumor type, location, and histologic composition. The alternative is to use many types of tissue in the vaccine. Animal-to-animal variation in regression following vaccination of a group of calves with a vaccine prepared from a single calf in the group has been attributed to more than one BPV type producing disease in the group. The stage of development is also important, and the virus is present in much greater concentration in the epithelial tissue of older warts than young ones. The vaccine can be administered subcutaneously, but better results are claimed for ID injection. Dosing regimens vary, but 2 to 4 injections 1 to 2 weeks apart are commonly recommended. Recovery in 3 to 6 weeks is recorded in 80% to 85% of cases where the warts are on the body surface or penis of cattle, but in only 33% when the warts are on the teats. The response of low, flat, sessile warts to vaccination is poor. Development of DNA vaccines for prophylaxis or therapy (which will likely use different genes) is active but experimental at this time.

Other treatments no longer commonly used include the injection into the wart of...
proprietary preparations containing antimony and bismuth or the intradermal injection of bacille Calmette–Guérin (BCG).

**CONTROL**

Specific control procedures are usually not instituted or warranted because of the unpredictable nature of the disease and its minor economic importance.

Vaccination has been shown experimentally to be an effective prevention method and gives complete protection in cattle against stiff experimental challenge. The vaccine must contain all serotypes of the papillomavirus because they are very type-specific.

Avoidance of close contact between infected and uninfected animals should be encouraged, and the use of communal equipment between affected and uninfected animals should be avoided.

**SARCOID**

**SYNOPSIS**

**Etiology** Locally aggressively benign fibroblastic tumors of the skin associated with bovine papillomavirus (BPV) types 1 and 2 (BPV-1 and BPV-2).

**Epidemiology** Common tumor of equids, including horses, donkeys, mules, and zebras. Breed differences in prevalence. Transmission by close contact and infection of wounds.

**Clinical findings** Single or multiple lesions in the skin of limbs, lips, eyelids, eye, penile sheath, and base of the ears. Can present as warty growth or have the appearance of granulation tissue or as nodules beneath the skin. Spontaneous regression is rare.

**Diagnostic confirmation** Histopathology.

**Treatment** None single treatment modality has an advantage. Surgical excision, cryosurgery, immunotherapy, radiation, and local chemicals (intraderal cisplatin, acyclovir) are used.

**Control** None recognized.

**ETIOLOGY**

The cause of sarcoid in horses, mules, and donkeys is associated with infection by bovine papillomavirus (BPV) types 1 or 2, and possibly BPV-13. 

Infection of young horses with BPV-1 virions induces nodular skin lesions 11 to 32 days after inoculation. DNA of both types can be demonstrated in sarcoid tumors by PCR, as can the major transforming gene of BPV, E5, although papillomavirus has not been isolated from these tumors, nor have papillomavirus particles been demonstrated.

Variants of BPV-1 associated with sarcoids in horses have greater activity in equine cells than in bovine cells, indicating some adaptation or predication of this variant for equine tissues. The causative virus (BPV-1 or BPV-2) appears to vary geographically, with ~80% of cases in western Canada associated with BPV-2, as opposed to reports from other countries in which BPV-1 predominates.

Genomic studies reveal that BPV-1 associated with sarcoids in horses likely diverged on multiple occasions from that in cattle at least 50,000 years before the present, and possibly much earlier, and well before domestication of either horses or cattle.

It is speculated that this is a nonproductive infection in which viral DNA exists episomally, and a “hit-and-run” mechanism for pathogenesis has been proposed, in which infection by the virus, which resolves, induces changes that then lead to neoplastic transformation of tissue.

However, given the demonstration of genetic susceptibility to sarcoid, the cause is almost certainly multifactorial, with virus infection being an inciting event in susceptible animals. There does not appear to be a role for mutation in the tumor suppressor gene, p53, in the development of sarcoid in horses.

**EPIDEMIOLOGY**

**Occurrence and Prevalence**

Horses, donkeys, mules and zebras are affected, as are giraffes and sable antelope.

Skin lesions histologically similar to those in equids also occur in felids. Equine sarcoid is the commonest neoplasm in horses, representing about 20% of all equine tumors diagnosed at necropsy, ~46% of all neoplastic skin lesions in horses at two sites in North America, and lesions in 21 of 68 horses examined in a first-opinion practice in the United Kingdoms.

Sarcoids were the histologic diagnosis in 42% of skin samples submitted to veterinary diagnostic laboratories in Canada.

Sarcoid tumors occur in 0.7% to ~11% of 3-year-old Swiss warmbloods and 0.4% of Freiberger horses in Switzerland. Sarcoids made up 53% of all tumors located on the head and body. Sarcoids occurred as solitary tumors in more than 99% of horses.

**Methods of Transmission**

Transmission can be by infection of wounds, and castration is thought to be a risk factor, with flies as possible vectors. Close contact may facilitate transmission. BPV DNA has been detected in flies (*M. autumnalis, M. domestica*) and biting stable flies (*S. calcitrans*) associated with horses and donkeys with sarcoids.

**Experimental Reproduction**

The disease has been transmitted with sarcoid tissue and cell free supernatant from minced sarcoid tumors. The disease has also been reproduced with bovine papillomavirus, although the experimentally produced tumors subsequently regressed, which seldom occurs with natural sarcoid.

**Animal Risk Factors**

Horses with sarcoids had a mean age of 7 years (95% CI, 7.9 to 8.5 years). Horses with fibroblastic sarcoids are younger (median age of 5 years, range 0.6 to 25 years) than those with nodular (median 7, range 1.0 to 23), occult (median 7, range 1.1 to 21), verrucose (median 6, range 0.5 to 19), or mixed (median 6, range 0.5 to 31) sarcoids. This wide age range highlights that sarcoids occur in young horses in addition to more aged animals. Risk of sarcoids was not associated with age or breed in two studies, but other studies report that Appaloosas, Arabian, and Quarter horses are at greater risk than are Standardbreds or Thoroughbreds. Donkeys were overrepresented in one study, and prevalence of disease was greater in populations of inbred zebra populations than in outbred populations (53% vs. 2%).
There is a genetically based susceptibility to the disease, and the predisposition of horses to sarcoid is associated with the type of major histocompatibility complex, although this association is not universally accepted. There are quantitative trait loci on equine chromosome (ECA) 20, 23, and 25 associated with genes that regulate virus replication and host immune responses. Approximately 40% of the susceptibility to the disease in Swedish Halfbred horses is attributable to an autosomal-dominant equine leukocyte antigen (ELA)-linked gene. However, Swiss Warmbloods are no more likely to have the disease if their parent is diagnosed with sarcoids than if the sire is free of the disease.

Environmental Risk Factors
Lesions commonly occur on traumatized areas.

PATHOGENESIS
The virus infects fibroblasts, and the infection is nonproductive. Viral DNA can be detected in lesional tissue, although viral load varies only slightly with clinical type of sarcoid. However, intralesional viral load is directly associated with the severity of the disease. It is thought that virus capsids of BVP are not found in equine sarcoids because papillomaviruses are usually host specific and the expression of virus capsids of the bovine papillomavirus requires the cellular environment of keratinocytes of the host species. Fibroblasts isolated from sarcoids are highly invasive, an attribute related to the high level of viral gene expression, matrix metalloproteinase upregulation, and production of viral oncoproteins. Protein products of E5 and E6 enhance cell proliferation and, in vitro, increased invasion in EqS02a cells, and E7 enhances independence of cell anchorage independence, all attributes of neoplastic cells. Elevated expression of phosphorylated p38 occurs in fibroblasts infected with BPV-1 as a result of the expression of BPV-1 E5 and E6 with enhancement of phosphorylation of the MK2 kinase, a substrate of p38. Fibroblastic sarcoid has a similar appearance to that of proud flesh or excessive granulation tissue. It is often a firm, fibrous nodule in the dermis, although the surface may be ulcerated. It is found most commonly at sites of previous wounds and also the eyelid and limbs.

• A combination of both of the forms just described (“mixed”)
• Occult sarcoid is typically an area of slightly thickened skin that has a roughened surface. It is usually partially hairless. Interference with these slow-growing sarcoids, including attempts at treatment, should be avoided; such interference can cause the tumor to proliferate. They occur most commonly around the mouth and eyes and on the neck.

CLINICAL PATHOLOGY
Confirmation of the diagnosis requires a biopsy specimen for histologic examination. Because sarcoids are usually associated with excessive granulation tissue and pyogranulomatous debris, the preferred specimen is a transverse section of the excised tumor. If punch biopsies are to be collected, then care should be taken that they include a representative section of the tumor, not just peripheral granulation tissue and edematous nontumor material. Examination by a pathologist accustomed to examining equine skin sections is important because the tumor has some features in common with papillomas and sarcomas and can be easily misdiagnosed.

PCR has been used to detect and quantify BPV DNA.

DIFFERENTIAL DIAGNOSIS
Cutaneous habronemiasis
Phycomycosis

TREATMENT
Surgical excision results in the return of the tumor in a significant proportion of animals within 6 months, often with overproliferation. BPV DNA can be detected in normal skin immediately surrounding sarcoids, and the recurrence has been speculated to reflect activation of latent BPV in normal tissue surrounding the tumor, although this interpretation is not supported by objective measurement of viral load in skin margins of the excised lesions.

Intralesional administration of cisplatin, an oncolytic agent with in vitro activity against sarcoids cells, by injection into the sarcoids or by electrochemotherapy, results in cure rates of 96% and 98%, respectively. The protocol for intralesional injection of cisplatin in sesame seed oil is as follows:

1. Crystalline lypophilized cisplatin powder is reconstituted with sterile water at a concentration of 10 mg/mL and mixed with medical-grade sesame seed oil (60%) and sorbitan monooleate (7%) by use of the pumping method just before administration (3.3 mg of cisplatin/mL of mixture).
2. Dosing objective is to deliver 1 mg of cisplatin per cubic centimeter of tumor. Tumor volume is calculated from the formula $V = \pi \times D_1 \times D_2 \times D_3/6$, where $D_1$ through $D_3$ are tumor diameters measured with Vernier calipers.
3. Four intratumoral administrations of cisplatin are given at 2-week intervals of a series of intratumoral and peritumoral injections in 1 or 2 parallel planes, depending on the tumor size. The cisplatin emulsion is injected through narrow-bore needles (22 or 25 gauge). The spacing between injection rows is uniform, with a separation of 6 to 8 mm. The spacing between planes of injection is approximately 1 cm. The largest dose of cisplatin to an adult horse should not be greater than 85 mg. Adverse reactions include moderate skin irritation. The treatment can be combined with surgical debulking of the lesion, with cisplatin administration begun when the surgical site has healed.

Administration of imiquimod 5% cream to sarcoids three times weekly resulted in a cure rate of 60% in a study involving 15 horses. Topical application of acyclovir (5%...

COWPOX AND BUFFALOPOX

SYNOPSIS
Etiology Cowpox virus and buffalopox virus are members of the genus Orthopoxvirus in the family Poxviridae. Buffalopox is a close variant of vaccinia virus.

Epidemiology Cowpox is endemic in the population of certain rodents in Europe and East Asia. Cattle are a rare and incidental host. Buffalopox is a (re)emergent disease occurring in buffaloes, cattle, and humans in India and neighboring countries. The natural host of buffalopox virus has not yet been identified. Spread of both viruses is by contact.

Clinical findings Typical pox lesions on the teats and udder. Erythema, papules, pustules, hemorrhagic crusts, proper ulcers, vesicles, and scab.

Clinical pathology Electron microscopy, polymerase chain reaction (PCR).

Diagnostic confirmation Electron microscopy, PCR, and virus isolation.

ETIOLOGY
Cowpox virus (CPXV) and buffalopox virus (BPXV) are members of the genus Orthopoxvirus in the family Poxviridae. Other orthopoxviruses infecting agricultural animals include horsepox, Usain Gishu, and camel-pox. All orthopoxviruses are antigenically extremely similar, but they can be identified by a combination of phenotypic and genetic tests.

CPXV received its name as a result of the association of this agent with skin lesions on the teat and udder skin of dairy cattle. Notwithstanding, it is probably a misnomer because infection of cattle is rare, whereas infection is widespread among rodents in Europe and western Asia.

EPIDEMIOLOGY
Occurrence Infection with CPXV is endemic in wild rodents such as voles (Microtus spp.) in Great Britain, Europe, and western Asia, with infection in different rodent species acting as the reservoir host in different geographic areas. Domestic cats are commonly infected from hunting rodents, but CPXV infection can occur in a number of different mammalian species, one of which is cattle. The clinical syndrome of cowpox in cattle is now extremely rare, but it occurs sporadically in Europe. In recent decades, reemergence of CPXV infections in cats, zoo animals, and humans has been reported.1

BPXV was first isolated in India in the early 1930s, and disease outbreaks affecting buffaloes, cattle, and humans have been reported in India, Nepal, Pakistan, Egypt, and Indonesia since then.2 BPXV is considered an important emerging or reemerging zoonotic viral infection in regions with a large buffalo population.3 A similar but distinct vaccinia-like virus has been associated with disease outbreaks among cattle and humans in Brazil.2

Origin of Infection and Transmission The origin of CPXV infection is most probably from infected farm cats or humans. Transmission from cow to cow within a herd is effected by milkers’ hands or teat cups. Spread from herd to herd is probably effected by the introduction of infected animals, by carriage on milkers’ hands, and in the absence of either of these methods, by transport by biting insects is possible. In a herd in which the disease is enzootic, only heifers and new introductions develop lesions. Milkers recently vaccinated against smallpox may serve as a source of infection for cattle, although the vaccinia virus, the smallpox vaccine virus, is a different virus.
BPXV is most commonly isolated from buffaloes, cattle, and people having direct and frequent contact with these animals. Although a primary host species functioning as virus reservoir has not yet been identified for BPXV, peridomestic rodents have been incriminated as potential vectors. Because disease outbreaks in buffalo herds are often associated with high disease occurrence among animal handlers and caretakers, transmission from animal to animal by means of people as vectors is considered to play an important role.

It is generally assumed that the virus gains access to tissues through injuries to teat skin, and extensive outbreaks are likely to occur when the environment is conducive to teat injuries. Spread is rapid within a herd and immunity is solid, so that the disease tends to occur in sharp outbreaks of several months in duration, with subsequent immunity protecting the cattle for at least several years.

Economic Importance
Losses are a result of inconvenience at milking time because of the soreness of the teats and from occasional cases of mastitis, which develop when lesions involve teat sphincters and decreased milk production.

Zoonotic Implications
Human cowpox is not common, although the disease incidence has increased over the past decades, an observation that has been explained by increasing susceptibility of the human population to poxvirus infection following discontinuation of smallpox vaccination in most parts of the world. Clinical cases in humans usually consist of one or a few lesions on the hand and face with minimal systemic reaction and are most commonly traced back to infected cats or occasionally rats rather than cattle.

An increasing incidence of clinical cases of BPXV and Brazilian vaccinia-like virus infection has been reported in humans, particularly among animal caretakers and animal handlers in India but also in Brazil, and has become a serious public health concern in some countries. Consumption of unpasteurized milk of affected animals has been incriminated as potential route of virus transmission from animal to human.

PATHOGENESIS
Five stages of a typical pox eruption can be observed. After an incubation period of 3 to 6 days, a roseolar erythema is followed by firm, raised papules light in color but with a zone of hyperemia around the base. Vesiculation, a yellow blister with a pitted center, follows. The subsequent pustular stage is followed by the development of a thick, red, tenacious scab.

In experimentally produced vaccinia virus mammillitis (produced by inoculation of smallpox vaccine), the lesions have three zones: a central brown crusty area of necrosis, surrounded by a gray–white zone of microvesicle formation, again surrounded by a red border as a result of congestion. The lesions are essentially hyperplastic.

CLINICAL FINDINGS
Typical lesions are similar for CPXV and BPXV infection and may be seen at any stage of development, but they are mostly observed during the scab stage, with the vesicle commonly having been ruptured during milking. True cowpox scabs are 1 to 2 cm in diameter and are thick, tenacious, and yellow–brown to red in color. In cows being milked, scab formation is uncommon, with the scab being replaced by a deep ulceration.

Distribution of the lesions is usually confined to the teats and lower part of the udder. Soreness of the teats develops, and milk letdown may be interfered with; the cow usually resents being milked. Secondary mastitis occurs in a few cases. Individual lesions heal within 2 weeks, but in some animals fresh crops of lesions may cause the disease to persist for a month or more. In severe cases, lesions may spread to the insides of the thighs, and rarely to the perineum, vulva, and mouth. Sucking calves may develop lesions around the mouth. In bulls, lesions usually appear on the scrotum.

Ulcerative skin lesions with raised edges frequently affected by secondary bacterial or fungal infection are commonly observed on the ears of nonlactating cattle and buffaloes infected with BPXV.

CLINICAL PATHOLOGY
The virus can be propagated in tissue culture, primarily on mouse L cells. The presence of virus-related DNA sequences can be identified by means of PCR.

DIFFERENTIAL DIAGNOSIS
A number of skin diseases may be accompanied by lesions on the udder and can easily be confused with cowpox if the lesions are advanced in age. Most outbreaks of teat skin disease that clinically resemble classical cowpox are associated with vaccinia virus from contact with a recently vaccinated person.

Pseudocowpox
Bovine ulcerative mammillitis associated with bovine herpesvirus-2 and bovine herpesvirus-4
Vesicular stomatitis and foot-and-mouth disease
Udder impetigo
Teat chaps and frostbite
Black spot

CONTROL
Prevention of spread is difficult because the virus responsible for the disease is readily transmitted by direct or indirect contact. Udder cloths, milking machines, and hands should be disinfected after contact with infected animals. Dipping of the teats in an alcoholic tincture of a suitable disinfectant, such as quaternary ammonium compounds, is usually satisfactory in preventing immediate spread. Although the prevalence and significance of CPXV infection in cattle is too low to warrant the development of vaccines, the emergence of buffalopox in buffalo and cattle herds and the ensuing zoonotic risk in some parts of the world may warrant considering the development of vaccines against BPXV for certain regions of the world.

REFERENCES

PSEUDOCOWPOX (MILKERS’ NODULE)

SYNOPSIS
Etiology Parapoxvirus.
Epidemiology Primarily affects cows in early lactation. Low, but progressive, morbidity in herd. Spread during milking.
Clinical findings Vesicles, pustules, formation of a thick scab elevated by granulating tissue. Key distinguishing feature is horseshoe-shaped ring of small scabs surrounding granulating tissue on the teat.
Clinical pathology Vesicle fluid for electron microscopy.
Diagnostic confirmation Electron microscopy.
Treatment Antiseptics and emollient ointment.
Control Milking hygiene.

ETIOLOGY
Pseudocowpox virus is a member of the genus Parapoxvirus, with close similarity to the viruses of infectious papular stomatitis of cattle and contagious ecthyma of sheep and goats. It is possible that pseudocowpox virus (PCPV) might be identical to bovine papular stomatitis virus (BPSV). The pseudocowpox virus was previously known as parapoxvirus bovis 2.

EPIDEMIOLOGY
Occurrence
Pseudocowpox is reported in most countries. In an affected herd the rate of spread is relatively slow and may result in the disease being present in the herd for up to a year. The morbidity rate approximates 100%, but at
any given time it varies between 5% and 10%, and occasionally up to 50%.

**Origin of Infection and Transmission**
The source of infection is infected cattle. The method of transmission includes physical transport by means of contaminated milkers' hands, washcloths, and teat cups. The virus cannot penetrate mucosa, and a preexisting discontinuity of it is necessary for the virus to gain entry. Transmission by biting insects seems likely. The virus can be isolated from the mouths of calves sucking affected calves, and from the semen of bulls.

**Animal Risk Factors**
Freshly calved and recently introduced cattle are most susceptible, but all adult cattle in a herd, including dry cows, are likely to be affected. The disease does not appear to occur in animals less than 2 years of age unless they have calved. There is no seasonal variation in incidence. Little immunity develops, and the disease is likely to recur in the herd within a short time.

**Economic Importance**
Pseudocowpox is relatively benign, with most losses occurring as a result of difficulty in milking and an increase in the incidence of mastitis.

**Zoonotic Implications**
The disease is transmissible to humans, with infection usually resulting in the development of milkers' nodule on the hand.

**PATHOGENESIS**
Transmission most commonly occurs at milking time and is mechanical, with the potential for transmission from cow to calf by sucking. The disease can be reproduced by the introduction of the virus onto scarified areas of skin. The lesions are characterized by hyperplasia of squamous epithelium.

**CLINICAL FINDINGS**
Acute and chronic lesions occur, and there may be up to 10 lesions on one teat (the udder is very rarely infected). Acute lesions commence as erythema followed by the development of a vesicle or pustule, which ruptures after about 48 hours, resulting in the formation of a thick scab. Pain is moderate and present only in the prescab stage. The scab, varying in size from 0.5 to 25 mm in diameter, becomes markedly elevated by developing granulating tissue beneath it; the scabs drop off 7 to 10 days after lesions appear, leaving a horseshoe-shaped ring of small scabs surrounding a small, wart-like granuloma, which may persist for months. The disease tends to disappear from a herd after 18 to 21 days but may recur cyclically about 1 month later. There are reports of lesions occurring occasionally in cows' mouths.

**Chronic lesions** also commence as erythema, but progress to a stage in which yellow–gray, soft, scurfy scabs develop. The scabs are readily rubbed off at milking, leaving the skin corrugated and prone to chapping. There is no pain, and the lesions may persist for months.

**Milkers' nodules** are clinically indistinguishable from human lesions associated with eczema virus. The lesions vary from multiple vesicles to a single, indurated nodule.

An outbreak of pseudocowpox infection occurred in Brazil, characterized by the presence of severe vesicular, papulopustular, and proliferative scabby lesions on the muzzle of 14 crossbred calves that did not have contact with dairy cattle. The lesions started as macules and papules on the muzzle that progressed to vesicles, pustules, and scabs with a clinical course of 10 to 15 days, at which time the lesions spontaneously resolved. Nucleotide sequencing of the virus isolated from the lesions revealed 97% homology with pseudocowpox virus and only 84% homology with bovine popular stomatitis virus.

**CLINICAL PATHOLOGY AND NECROPSY FINDINGS**
Material for examination by tissue culture or electron microscopic examination, the latter being highly recommended as a diagnostic procedure, should include fluid from a vesicle.

**DIFFERENTIAL DIAGNOSIS**
Differentiation of those diseases in which lesions of the teat are prominent is dealt with in the preceding section on cowpox.

**TREATMENT**
Locally applied ointments of various kinds appear to have little effect on the lesions. The recommended treatment includes the removal of the scabs, which should be burned to avoid contaminating the environment, application of an astringent preparation, such as triple dye, after milking and an antiviral effect. An effort should be made to reduce teat trauma because infection is facilitated by discontinuity of the skin.

**REFERENCES**

**LUMPY SKIN DISEASE**

**SYNOPSIS**

**Etiology**
Lumpy skin disease virus, of the genus Capripoxvirus (closely related to sheep and goatpox viruses).

**Epidemiology**
Previously enzootic in sub-Saharan Africa, but expanded into most of Africa in the 1970s. The disease is now actively spreading in the Middle East, with outbreaks in Israel, Lebanon, Turkey, Syria, Iran, Azerbaijan, and North Cyprus. Epizootics interspersed with periods of sporadic occurrence. Transmission by contact and a range of sucking/biting arthropod vectors.

**Clinical findings**
Fever, nodular lesions on the skin and mucous membranes and lymphenadenopathy. A proportion of cattle develop generalized infection, with high mortality. Losses accrue from damage to hides, decreased milk yield and growth, abortion, deaths, and disruption of international trade. Necrotic plugs of tissue highly susceptible to secondary infection and flystrike.

**Clinical pathology**
Intracellular, eosinophilic inclusion bodies in biopsy material. Virus isolation. Fluorescent antibody, serum neutralization, and polymerase chain reaction (PCR) tests.

**Necropsy findings**
Nodules in skin, upper alimentary tract, respiratory tract.

**Diagnostic confirmation**
Biopsy and histology. Virus isolation to differentiate from pseudo lumpy skin disease caused by bovine herpesvirus-2.

**Treatment**
Supportive.

**Control**
Vaccination, control of movement of cattle from affected areas.

**ETIOLOGY**
Lumpy skin disease (LSD) is a severe systemic disease of cattle associated with the Neethling poxvirus, a Capripoxvirus. It has close antigenic relationship to sheeppox and goatpox viruses, which are in the same genus. There appears to be a difference in virulence between strains.

**EPIDEMIOLOGY**
**Occurrence**
The disease used to be confined to sub-Saharan Africa, but spread to many other African countries in the 1970s, then Egypt (outbreaks occurred in 1988 and 2006; the disease is now enzootic) and Israel (outbreaks in 1989, 2006-2007, and 2012). In Israel it was initially eradicated by slaughter of infected and in-contact animals, but vaccination using Sheeppox, and more recently Neethling strain vaccine, has since been used. The virus is actively spreading within and from the Middle East, with cases...
confirmed in Kuwait (1991), Lebanon (1993), the United Arab Emirates (2000), Bahrain (2003), Oman (2010), Turkey and Syria (2013), Jordan (2013), Iran and Iraq (2013), Azerbaijan and North Cyprus.\textsuperscript{1,2} There is a risk it could be introduced into European countries, mainly through the illegal movement of animals but also within vectors.\textsuperscript{2,3}

Some outbreaks are associated with severe and generalized infections and a high mortality rate, whereas others have few obviously affected animals and no deaths. In general, outbreaks are more severe following introduction of the infection into a region and then abate, probably associated with the development of widespread immunity. Morbidity rates can reach 80\% during epizootics, but typically range from 10\% to 30\% in enzootic areas. In Kenya, the disease is milder, with a lower morbidity rate and an average case fatality of 2\%. Outbreaks in Israel produced no direct mortality from the disease. A resurgence of the disease in South Africa was associated with higher rainfall and a decrease in the use of vaccination.

**Origin of Infection and Transmission**

The virus is present in the nasal and lacrimal secretions, semen, and milk of infected animals. However, direct contact is not thought to be the major source of transmission, with most cases associated with transmission by an arthropod vector. LSD virus has been isolated from *S. calcitrans* and *M. conficta* and transmitted experimentally using *S. calcitrans* and *Abylloma* and *Rhipicephalus* ticks, with evidence the virus may be transmitted vertically and overwinter in these tick species.\textsuperscript{2,7} Other vectors are suspected, including *Biomyia*, *Culicoides*, *Glossina*, and *Musca* spp. However, although the virus was detected in mosquitoes (*Anopheles stephensi*, *Culex quinquefasciatus*), stable flies, and biting midges (*Culicoides nebulosis*) after feeding on cattle with lumpy skin disease, infection did not transmit to susceptible cattle when these arthropods were subsequently allowed to feed on them.

Transmission via infected semen used in artificial breeding has been demonstrated experimentally.\textsuperscript{9}

**Risk Factors**

**Animal Risk Factors**

All ages and types of cattle are susceptible, although very young calves and lactating and malnourished cattle develop more severe clinical disease. Recently recovered animals are immune for about 3 months.

British breeds, particularly Channel Island breeds, are much more susceptible than zebu types, both in numbers affected and the severity of the disease. Wildlife species are not affected in natural outbreaks, although there is concern that they might be reservoir hosts in interepidemic periods, such as African buffalo (*Syncerus caffer*) in the Kruger National Park in South Africa.\textsuperscript{7}

Typical skin lesions, without systemic disease, have been produced experimentally with Nethling virus in sheep, goats, giraffes, impalas, and Grant’s gazelles, but wildebeests were resistant. Natural cases of lumpy skin disease were recorded in water buffalo (*Bubalis bubalis*) during an outbreak in Egypt in 1988, but morbidity was much lower than for cattle (1.6\% vs. 30.8\%).

**Environmental Risk Factors**

Outbreaks tend to follow waterways. Extensive epizootics are associated with high rainfall and high levels of insect activity, with peaks in the late summer and early autumn. Introduction of new animals and communal grazing have been identified as risk factors for LSD infection in Ethiopia.\textsuperscript{8}

**Pathogen Risk Factors**

Capripoxviruses are resistant to drying and able to survive freezing and thawing, but most are inactivated by temperatures above 60\°C (140\,F).

**Experimental Transmission**

Experimental transmission can be achieved with ground-up nodular tissue, blood, or virus grown in tissue culture given by intranasal, ID, or IV routes. Although lumpy skin disease is characterized by generalized nodular skin lesions, less than 50\% of natural or experimental infections develop generalized skin nodules. The length of viremia is not correlated with the severity of clinical disease.

**Economic Importance**

The mortality rate is usually low (although it can be 10\% or more), but economic losses are high. There is reduced feed intake, a reduction in milk production, and occurrence of secondary mastitis associated with lesions on the teats. Losses also accrue from hide damage, reduced body condition, decreased fertility in bulls, and abortion in cows. There has always been a high risk of LSD spreading out of Africa, and it is now actively spreading in the Middle East. It is also a potential agent for agricultural bioterrorism.

**PATHOGENESIS**

In the generalized disease there is viremia and fever, followed by localization in the skin and development of inflammatory nodules. Following ID inoculation, local lesions develop at the challenge site but without viremia and systemic infection.

**CLINICAL FINDINGS**

The incubation period is typically 2 to 4 weeks in field outbreaks and 7 to 14 days following experimental challenge. In severe cases there is an initial rise of temperature, which lasts for over a week, occasionally accompanied by lacrimation, nasal discharge, salivation, and lameness. Multiple intradermal nodules appear suddenly about a week later, often initially on the perineum. They are round and firm, 1 to 4 cm in diameter, and flattened, and the hair on them stands on end. They vary from a few to hundreds and, in most cases, are confined to the skin. However, lesions can occur elsewhere, such as in the nostrils and on the turbinates, causing mucopurulent nasal discharge, respiratory obstruction, and snoring; in the mouth, as plaques and then ulcers, causing salivation; on the conjunctiva, causing severe lacrimation; and on the prepuce or vulva, spreading to nearby mucosal surfaces. In most cases the nodules disappear rapidly, but they may persist as hard lumps or become moist and necrotic, then slough.

Lymph nodes draining the affected area become enlarged, and local edema can occur, particularly of the limbs. When the yellow center of nodules slough, this can expose underlying tissues, including testicles or tendons. Lesions where skin is lost may remain visible for long periods. When lesions coalesce, large areas of raw tissue can be exposed, and these are susceptible to invasion with screwworm fly larvae. Lesions in the respiratory tract are often followed by pneumonia.

Convalescence usually takes 4 to 12 weeks, and pregnant cows may abort.

**CLINICAL PATHOLOGY**

The virus can be cultivated from lesions, and the viral antigen can be detected by a variety of PCR tests. Viral DNA can be detected in the skin up to 90 days after infection using PCR, which is much longer than the virus can be isolated. An antigen ELISA has also been used with samples collected early in the course of the disease, before the development of neutralizing antibodies. Electron microscopy will identify capripox virions in skin biopsies or scabs. This must be used in combination with the history of generalized nodular skin disease; capripox can be distinguished from parapoxvirus (the agent of bovine papular stomatitis) and pseudocowpox, but it is morphologically similar to cowpox and vaccinia viruses. Histopathology of lesions reveals a granulomatous reaction in the dermis and hypodermis, with intracellular, eosinophilic inclusion bodies in early lesions.

Virus neutralization is the most specific serologic test, but immunity is predominately cell mediated, and thus it may fail to detect low concentrations of antibodies in many exposed cattle. The agar gel immunodiffusion (AGID) and indirect fluorescent antibody tests are less specific, producing false positives as a result of cross-reaction with bovine papular stomatitis and pseudocowpox viruses.

**NECROPSY FINDINGS**

The skin lesions are described under “Clinical Findings.” Similar lesions are present in the mouth, pharynx, trachea, skeletal muscle,
from uninfected to infected areas is an important measure to prevent the introduction of the virus. Once in an area, control is by vaccination.

Vaccination
Freeze-dried, live attenuated vaccines are commercially available and the most commonly used. There is antigenic homology between the Capripoxviruses, and thus vaccination of cattle with attenuated sheeppox virus has been used to protect against infection with LSD virus. This was used in countries previously free of LSD virus because it eliminated any risk of escape of attenuated live vaccine virus from vaccinated herds. However, incomplete protection with a vaccine based upon what was thought to be a Kenyan sheep and goatpox occurred during a 2006 outbreak of LSD in Egypt, and following the use of a sheeppox vaccine in Israel in 2006-2007 in which 11% of vaccinated cattle developed skin lesions. Consequently, the attenuated Neethling strain vaccine of LSD virus was used in response to a serious outbreak of the disease in Israel during 2012. A battery of three molecular tests was able to differentiate infection with the vaccine strain, and a virulent virus was developed; no spread from vaccinated to nonvaccinated cattle was recorded.

A small percentage of cattle vaccinated with the sheeppox virus do develop local granulomatous reactions, but there is no spread of the virus to sheep running with the cattle. However, the commonly used Kenyan sheeppox and goatpox vaccine virus (designated O-240) has been identified as an LSD virus; the low attenuation of this virus probably makes it unsafe for cattle because of its potential to cause clinical disease in vaccinated animals. Other viruses capable of infecting sheep, goats, and cattle have been identified as potential candidates for vaccines against all capripox diseases.

Vaccination of a herd at the start of an outbreak is of limited use. Most animals will already be incubating the disease, and poor needle hygiene in these circumstances may spread the disease. Slaughter of affected and in-contact animals, destruction of contaminated hides, and vaccination of at-risk animals is a common approach when the disease is introduced to a previously free country.

SHEEPPOX AND GOATPOX

SYNOPSIS
Etiology Capripoxvirus. Strains vary in virulence and host specificity.

Epidemiology Highly contagious, spread by aerosol, contact, and flies. Young and nonindigenous animals more susceptible. Morbidity and case-fatality rates are high.

Clinical findings Fever, generalized skin and internal pock lesions, lymphadenopathy, mucopurulent nasal discharge, high mortality.

Clinical pathology Fluorescent antibody and electron microscopy of biopsy material, serology, virus isolation.

Necropsy findings Pox nodular lesions in alimentary tract and respiratory tract.

Diagnostic confirmation Fluorescent antibody staining, virus isolation.

Control Vaccination.

ETIOLOGY
Sheeppox, goatpox and lumpy skin disease of cattle are members of the genus Capripoxvirus, one of six genera of poxviruses. The diseases produced by sheeppox and goatpox viruses are collectively called capripox infections. They are named on the basis of their host specificity in natural outbreaks and are usually highly host specific in natural infections, although exceptions exist. For example, Kenya sheeppox and goatpox viruses, and Yemen and Oman sheep isolates, infect both sheep and goats, although the disease caused by the same isolate can vary dramatically between the two hosts. The viruses are closely related genetically, and hence they cross-react in serologic tests, and many can cross species barriers in experimental infections. Recombination may also occur naturally between isolates from different host species.

EPIDEMIOLOGY
Prevalence of Infection
Sheeppox and goatpox are prevalent in North and Central Africa north of the equator, the Indian subcontinent, the Middle East, China, Southwest Asia, and the former Soviet Union. Sporadic outbreaks occur in...
Diseases

Lesions. In susceptible flocks and herds, mor-
virus infections of small ruminants are the most serious of all the pox diseases in animals, characterized by fever and skin lesions. In susceptible flocks and herds, morbidity is 75% to 100%, with outbreaks often causing death in 10% to 85% of affected animals depending on the virulence of the infecting strain.

Methods of Transmission
Sheeppox and goatpox are highly contagious. The virus enters via the respiratory tract, and transmission commonly is by aerosol infection associated with close contact with infected animals. The virus is present in nasal and oral secretions for several weeks after infection and can live in scabs that have fallen off the animal for several months. Spread can also occur from contact with contaminated materials and through skin abrasions produced iatrogenically or by insects. Capripox has been shown to spread via the bites of S. calcitrans and the tsetse fly.

Experimental Reproduction
The disease can be transmitted by intradermal, intravenous, and subcutaneous inoculation and by virus aerosols. Capripox antigen is detected 6 and 8 days postinfection in skin lesions and by virus aerosols. Capripox antigen appears in cells of the monocytes/macrophages as described previously for the infecting strain.

Zoonotic Implications
Human infections in people handling infected animals are not a consideration.

PATHOGENESIS
During an initial viremia, the virus is carried by infected monocytes/macrophages to many tissues, particularly the skin, respiratory tract, and gastrointestinal tract. Symptomatic cells are seen in skin, and these probably facilitate local spread of the virus. The development of typical pox lesions, as in vaccinia, is characteristic of the disease. The virus is present in greatest quantities from 7 to 14 days after inoculation. Passive protection by serum will protect against challenge. Circulating antibody limits spread of infection, but does not prevent replication of the virus at the site of inoculation.

CLINICAL FINDINGS
In sheep, sheeppox has an incubation period of 12 to 14 days, with the malignant form being the most common type in lambs. There is marked depression and prostration, a very high fever, and discharge from the eyes and nose. Afflicted lambs may die during this stage before typical pox lesions develop. When pox lesions develop, they appear on unwooled skin and on the buccal, respiratory, digestive, and urogenital tract mucosae. They commence as papules, then become nodular, occasionally vesicular, and pustular, then finally scab. Some progress from nodules to tumor-like masses. The mortality rate in this form of the disease may reach 50%. In the benign form, more common in adults, only skin lesions occur, particularly under the tail; there is no systemic reaction, and animals recover in 3 to 4 weeks. Abortion and secondary pneumonia are complications. In sheep, infection with goatpox is more severe than with sheeppox, with lesions on the lips and oral mucosa, teats, and udder.

Goatpox in goats is very similar clinically to sheeppox in sheep. Young kids suffer a systemic disease, with lesions spread generally over the skin and on the respiratory and alimentary mucosae. Adult goats may have systemic disease and extensive lesions, but in adult goats the disease is usually mild, and lesions are as described previously for the benign form in sheep. A flat hemorrhagic form of capripox is seen in some European goats, and this form has a high case-fatality rate.

Economic Importance
Loss is from mortality, abortions, mastitis, loss of wool, skin condemnation, and loss of exports. In ewes and does, severe losses may occur if the udder is invaded because of the secondary occurrence of acute mastitis. In some outbreaks, adult sheep are affected with the more severe form of the disease. Sheeppox is a potent threat to countries that have large sheep populations, and

CLINICAL PATHOLOGY
Antigen Detection
Diagnosis is based on typical clinical signs combined with laboratory confirmation of the presence of the virus or antigen. Using electron microscopy, large numbers of characteristic “sheeppox cells” containing inclusion bodies and typical capripox virions can be seen in biopsies of the skin. The virus can be cultured in tissue culture, but virus isolation as a method of rapid diagnosis is limited by the extended time it takes for virus cytopathic effects to develop and the need, with some strains, for several blind passages before this occurs. Direct fluorescent antibody testing is used to detect the presence of poxvirus in the edema fluid, and the antigen can be detected in biopsies of lymph glands by AGID using specific immune sera. An antigen detection ELISA is also available.

SeroLOGY
Serologic testing can be by virus neutralization, which is 100% specific, or by an indirect fluorescent antibody or an agar gel precipitation test (AGPT), both of which cross-react with antibody to orb virus. An indirect ELISA has a similar diagnostic sensitivity and slightly lower specificity than the virus neutralization assay. Virus-specific analysis of antibody response by Western blot can differentiate the infections.

PCR and melt-point analyses for the detection of capripox antigen have been developed, some as duplex or multiplex assays to differentiate capripox infections from orb virus. These are suitable for use in countries that do not have the disease and do not hold live capripox virus. Loop-mediated isothermal amplification (LAMP) assays are potentially a cost-effective test to rapidly differentiate sheeppox and goatpox during outbreaks.

Necropsy Findings
In the malignant form, pox lesions extend into the mouth, pharynx, larynx, and vagina, with lymphadenopathy and a hemorrhagic spleen. Lesions may also appear in the trachea. Lesions in the lung are severe, manifesting as lentil-sized white pox nodules to a consolidating and necrotizing pneumonia. Lesions occasionally reach the abomasum and are accompanied by hemorrhagic enteritis.

Histologically, cells infected with capripox virus have a characteristic appearance with vacuolated cytoplasm and nuclei, margined chromatin, and multiple inclusion bodies (“sheeppox cells”). With the use of double immunohistochemical labeling, the viral antigen appears in cells of the monocyte/macrophage lineage within 6 to 8 days of infection, and later in pneumocytes.

Differential Diagnosis
Contagious ecthyma (orf) Bluetongue
**TREATMENT**

No specific treatment is advised, but palliative treatment may be necessary in severely affected animals.

**CONTROL**

Control in countries or regions that are free of this disease centers around prohibiting the importation of live animals and unprocessed produce from infected areas and, if the infection is introduced, ring vaccination, the destruction of affected flocks, and the quarantine of infected premises.

Vaccination with natural lymph has been used in some affected areas, but it can spread the disease. Natural infection with one capripox strain imparts immunity to all capripox infections, and vaccination with a single capripox vaccine will give protection across all species and against all capripox infections.

A variety of commercial vaccines are available, and there is no easy basis for comparison. Killed virus vaccines elicit only temporary protection, but live attenuated vaccines protect against infection for more than 1 year. Colostral antibody can interfere with vaccination until 6 months of age. Vaccination programs in endemic areas recommend vaccination of lambs at 2 and 10 weeks, followed by an annual booster. A subunit capripox virus vaccine has been developed.

Vaccination in the face of outbreak is unlikely to prevent deaths during the subsequent 2 weeks and, if needle hygiene is poor, may facilitate the spread of the disease.

**REFERENCES**

**ETIOLOGY**

Orf is associated with the orf virus, a type species of the genus Parapoxvirus (family Poxviridae). In addition to the orf virus (parapox ovis), the genus includes the viruses of bovine papular stomatitis (parapox bovis 1), pseudocowpox (parapoxvirus bovis 2), and a parapox virus of deer. The orf virus withstands drying and is capable of surviving at room temperature for at least 15 years. Restriction endonuclease digests of DNA shows considerable heterogeneity between different field isolates.

**EPIDEMIOLOGY**

**Occurrence**

The disease occurs worldwide in sheep and goats. It causes unthriftiness, varying degrees of pain, and some economic loss. It occurs most commonly in 3- to 6-month-old lambs at pasture, although lambs 10 to 12 days of age and adult animals can be severely affected. Outbreaks involving the lips and face of young lambs and the udders of the ewes are common. This disease can occur at any time, but outbreaks are most common in grazing sheep during dry conditions, lambs in feedlots, and penned sheep being fed from troughs. The disease has occurred in musk ox, in which it causes heavy losses, and in reindeer, mountain goats and bighorn sheep, chamois, caribou, Dall sheep, buffalo, wild goats, and camels. The virus can be passed in rabbits if large doses are placed on scarified skin or injected ID. Mild lesions develop on the chorioallantois of the 9- to 12-day-old chick embryo. Guinea pigs and mice are not susceptible.

The disease also occurs in humans working among infected sheep. In abattoir workers it is most common in those handling wool and skins.

**Morbidity and Case Fatality**

Outbreaks may occur in sheep and goats, with morbidity rates approaching 100% and case-fatality rates from 5% to 15%. The deaths that occur are a result of the extension of lesions in the respiratory tract, but the case fatality rate may reach 15% if severely affected lambs are not provided with adequate care and support, or if secondary infection and cutaneous myiasis (flystrike) are allowed to occur. In the rare outbreaks where systemic infection occurs, the case-fatality rate averages 25% and may be as high as 75%. Under field conditions, recovered animals are immune for 2 to 3 years, but no antibodies appear to be passed in the colostrum, and newborn lambs of immune ewes are susceptible.

**Methods of Transmission**

Scabs that fall off from healing lesions contain the virus and remain highly infective for long periods in dry conditions, but survival of the disease in a flock may be the result of chronic lesions that exist for long periods on individual animals. Infection can be from environmental persistence of the virus or from infected sheep. Spread in a flock is very rapid and occurs by contact with other affected animals or by contact with contaminated inanimate objects, such as feed troughs or ear-tagging pliers. An outbreak of lesions on the tail has been recorded in association with the use of docking instruments.

It has been assumed that natural infections on pasture are the result of invasion of the virus after skin damage induced by prickly plants or stubble; application of a viral suspension to scarified skin is the established method of inducing orf. However, an outbreak has occurred in groups of lambs collected from several farms and transported in a vehicle over a period of 23 hours when there was no evidence of injury to their mouths.

**Experimental Reproduction**

The disease is readily reproduced by introduction of the virus onto scarified areas of
skin. Immunity to reinfection is relatively solid at the site of initial infection, but shorter-duration lesions can be reproduced by rechallenge of these sheep at other sites.

**Risk Factors**
The primary risk factors are the presence of the virus and the immune status of the sheep. Mixing of sheep, such as occurs in a feedlot with sheep originating from several sources, allows transmission of the infection. Intercurrent infections may exacerbate the occurrence of disease on rare occasions. For example, the disease has spread from clinically normal ewes to susceptible 2- to 4-year-old ewes that were persistently infected with border disease virus. Lambs experimentally infected with *Ehrlichia phagocytophilia* and subsequently challenged with orf virus developed more severe lesions with a longer course than those in control lambs.

**Economic Importance**
The disease produces only a minor setback, except when it affects young sucking lambs with associated lesions on the teats and udders of their ewes. Loss from lamb mortality and secondary mastitis in these circumstances can be significant.

The disease assumed economic importance for Australia when shipments of sheep exported from Australia in 1989 to 1990 were rejected at some ports in the Middle East because of scabby mouth. Litigation is also a potential concern when zoonotic infections occur at petting zoos or fairs.

**Zoonotic Implications**
Orf virus is readily transmitted to humans and historically has been a risk for industrial workers handling raw wool.

Lesions occur at the site of infection, usually an abrasion infected while handling diseased sheep for shearing, crutching, or drenching, or by accidental inoculation with live scabby mouth vaccine. Lesions progress from macular to papular stages, are usually single, and are localized on the hands, arm, or face. The lesions are self-limiting and heal without scarring after 6 to 7 weeks. They are pruritic and respond poorly to local treatment. Orf is also a zoonotic consideration in petting zoos and fairs where children allow lambs to suck their fingers or otherwise become infected from handling sheep in interactive exhibits.

**PATHOGENESIS**
Damage to the skin is essential for the establishment of orf infection and the development of typical lesions. Following viral challenge of mildly abraded skin, the virus does not establish in the damaged epidermis, but instead replicates in the cells of an underlying replacement epidermal layer derived from the walls of the wool follicles. Following scarification of ovine skin and topical application of the orf virus, antigen cannot be detected in the skin during the period when the epidermis is being renewed. The virus can first be detected in the center of the newly differentiated epidermis immediately below the stratum corneum, 72 hours after infection. The location of the virus during the eclipse stage is unknown. The infection spreads laterally and uniformly from the new epidermis, initially in the outer stratum spinosum and subsequently throughout the entire depth of the epidermis. The skin reaction consists of a cellular response with necrosis and sloughing of the affected epidermis and underlying stratum papillare of the dermis. The cutaneous response to infection includes a delayed-type hypersensitivity reaction and an influx of inflammatory cells involving neutrophils, basophils, and possibly mast cells. Class II dendritic cells are also involved and appear to form the basis of a highly integrated local dermal defense mechanism. The lesions evolve through the stages of macule, papule, vesicle, pustule, scab formation, and resolution. The pustules develop within a few days and then rupture, resulting in ulcers and subsequently the formation of a thick overlying crust or scab that is shed within 3 to 4 weeks, leaving no scar. Immunity is solid but will last only about 8 months. Although there is an antibody immune response to the virus, recovery is the result of cell-mediated immune mechanisms. Experimentally, a secondary infection, following recovery from a primary infection, is milder and accelerated. During the secondary challenge, pustules and scabs develop earlier, the lesions resolve more rapidly, and no vesicular stage may occur.

**CLINICAL FINDINGS**

**Sheep**
Lesions develop initially as papules and then pustules, stages that are not usually initially seen, and progress to a raised and moderately proliferative area of granulation and inflammation covered with a thick, tenacious scab. Time from the initial lesions to the formation of scabs is approximately 6 to 7 days. New lesions will develop during the first 10 days of infection. The first lesions develop at the oral mucocutaneous junction, usually at the oral commissures, and are accompanied by swelling of the lips. From here they spread to the muzzle and nostrils, the surrounding hairied skin, and, to a lesser extent, to the oral mucosa. They may appear as discrete, thick scabs 0.5 cm in diameter, or coalesce and be packed close together as a continuous plaque. Fissuring occurs, and the scabs are sore to the touch. They crumble easily but are difficult to remove from the underlying granulation. Affected lambs suffer a severe setback because of restricted sucking and grazing. In benign cases the scabs dry and fall off, and recovery is complete in about 3 weeks.

Affected lambs sucking ewes may cause spread of the disease to the udder, where a similar lesion progression is seen on the teats (Fig. 16-6).

Lesions on the teats predispose to mastitis, and secondary infection of the skin lesions by bacteria or fly larvae occurs in some cases. In rams, lesions on the scrotum may be accompanied by fluid accumulation in the scrotal sac and associated temporary infertility. A high incidence of infection can also occur where the dominant lesions are on the feet, occurring around the coronary band, the dew claws, and on the volar areas of the intervening skin.

Occasionally severe edema of the face can occur in association with oral lesions. In a severe case, over 50% of 4-month-old Texel lambs grazing good-quality pastures in Ireland were affected.2 The edema resolved after 10 days but appeared quite similar to that seen with experimental bluetongue infections.

Rarely, systemic invasion occurs and lesions appear on the coronets and ears, around the anus and vulva or prepuce, and on the nasal and buccal mucosas. There is a severe systemic reaction, and extension down the alimentary tract may lead to a severe gastroenteritis; extension down the trachea may be followed by bronchopneumonia. Lesions may also occur in the mouth, involving the tongue, gums, dental pad, or a combination of those sites. These are more commonly seen in outbreaks affecting lambs less than 2 months of age. In the mucosa of the mouth these lesions do not scab but are papular erosive and surrounded by an elevated zone of hyperemia. Extensive painful and proliferative lesions occur on the gingival margins of the incisor teeth.
In some outbreaks the lesions on the skin are highly proliferative and present as raw, raised, granulating lesions without an overlying scab. This manifestation appears more common in Suffolk sheep, and lesions are present on the lips, bridge of the nose, and around the eyes (Fig. 16-7). Cases of this proliferative form involving the feet are also recorded.

A malignant form of the disease has also been observed in sheep. It begins with an acute episode manifested by oral vesicles, followed by extension of these lesions down the gastrointestinal tract, followed later by granulomatous lesions and shedding of hooves.

An atypical case of the disease in sheep after extensive cutaneous thermal injury has been described. The virus was present in proliferative verrucous tissue lesions at the periphery of the original thermal injury. The lesions consisted of tightly packed 0.5-mm-diameter papillary projections.

Goats
An unusual case in a group of female goats has been described, with multifocal lesions over the head, neck, thorax, and flanks of each animal. The lesions developed approximately 2 weeks after the animals returned from a show at which the does were housed for 3 days in pens previously occupied by sheep. The lesions began as plaques, followed by epidermal proliferation and severe encrustation. Affected areas were discrete by epidermal proliferation and severe edema and damage to the ears.

Persistent orf occurred in a proportion of Boer goats following an outbreak. In most animals the disease ran a typical clinical course of 3 to 4 weeks, but in 2% of animals it persisted for several months, with lesions disseminated over the body. There were no particular distinguishing differences of the virus genome compared with those of other orf viruses, and the persistence was possibly a result of individual host-susceptibility factors.

**CLINICAL PATHOLOGY**
Electron microscopic identification of the virus is quick and generally reliable with multiple samples from an affected herd or flock. Viral DNA can also be detected by a number of PCR assays, including real-time PCR and a multiplex PCR to differentiate orf, sheeppox, and capripox viruses. LAMP assays have also been developed. These are comparable to a real-time PCR but require less sophisticated equipment and thus may be a suitable test where resources are limited but rapid differentiation of orf virus and poxviruses is necessary.

Recovered animals have elevated neutralizing antibodies in their serum that are detectable by a gel diffusion test. Other serologic tests have been developed but are not widely available and probably of little clinical value.

**NECROPSY FINDINGS**
In malignant cases there are irregularly shaped lesions with a hyperemic border in the oral cavity and the upper respiratory tract, with rare involvement of the mucosa of the esophagus, abomasum, and small intestine. Typical lesions are actually proliferative, with subsequent loss of centrally located cells creating an ulcer-like appearance. Microscopically, the hyperplastic epithelium contains swollen degenerate cells, some of which may house eosinophilic cytoplasmic inclusion bodies.

**Samples for Confirmation of Diagnosis**
- **Histology**—formalin-fixed lesions (LM)
- **Virology**—vesicle fluid, scraping from lesion (EM)

**DIFFERENTIAL DIAGNOSIS**
In most outbreaks of ecthyma, the cases are sufficiently mild to cause no real concern about losses or about diagnosis.

Dramatic outbreaks of a very severe form of the disease may occur and may be confused with bluetongue. Very severe cases are also commonly seen in housed experimental sheep, especially colostrum-free lambs.

**Ulcerative dermatosis** is sufficiently similar to cause confusion in diagnosis, but this disease has not been reported for many years.

**Mycotic dermatitis** usually occurs on woolled skin, but lesions can occur on the lips and feet (strawberry footrot), have a thick dry asbestos-like scab, and are easily differentiated by laboratory culture.

**Facial eczema** is distinguished by diffuse dermatitis and severe edema and damage to the ears.

**Papillomatosis (warts)** need also to be considered in the differential diagnosis for the proliferative manifestations of contagious ecthyma, although warts are extremely uncommon in sheep.

**Bluetongue** is always accompanied by a high mortality rate and a severe systemic reaction, and lesions occur on the muzzle, the coronets, and extensively on the buccal mucosa. It is more common in adults than sucking lambs. Because it is transmitted by insect vectors, the morbidity rate is usually much less than the 90% commonly seen in contagious ecthyma.

**Sheeppox** may present a rather similar clinical picture, but the lesions are typical and there is a severe systemic reaction and heavy mortality rate.

**Foot-and-mouth disease.** The classic developed lesions of orf are easily differentiated from foot-and-mouth disease, but the papular and vesicular stages seen early in the course of orf, particularly lesions in the mouth, can be difficult to differentiate, especially when a prompt on-farm differentiation is required. The raised, firm, papular erosive nature of the lesion with the surrounding zone of hyperemia is a crucial differentiating feature in the field.

---

Fig. 16-7 Extensive chronic lesions as a result of chronic orf infection in a Suffolk ewe lamb. These facial lesions are often accompanied by similar lesions on the distal limbs.
TREATMENT

Removal of the scabs and the application of ointments or astringent lotions are practiced but delay healing in most cases. Antiviral drugs have been combined with emollients in gels and sprays (e.g., cidofovir and sucralfate). These formulations can decrease the time to healing and amount of virus shed in scabs, but will be impractical and not cost-effective in most flocks. Supportive treatment, such as providing soft, palatable food, may be helpful.

CONTROL

In the early stages of an outbreak, the affected animals should be isolated and the remainder vaccinated. Vaccination is of little value when a large number of animals are already affected. Persistence of the disease from year to year is common. If lesions are severe and consistently provide a setback, lambs should be vaccinated at 6 to 8 weeks of age. Vaccination when a few days old evokes a protective response. However, prelambing vaccination of the ewe is of no benefit for the lamb and so is not recommended. Vaccination of housed lambs should be given before the time that lesions have been observed in previous years.

Commercially available vaccines are typically a suspension of live tissue culture virus, often with a blue dye. An autogenous vaccine can also be prepared from a suspension of scabs in glycerol saline. The vaccine is scratched in a 5-cm line onto bare skin, usually the inside of the foreleg, brisket, or inner thigh. Alternative methods are to apply autogenous vaccine to a small area of scari
ded skin or to prick the ear with a needle dipped in the vaccine. Vaccination is effective for at least 2 years, but the lambs should be inspected 1 week after vaccination to check that a local reaction has occurred. A small proportion of vaccinated lambs may develop mild lesions around the mouth because of nibbling at the vaccination site. Absence of a local reaction signifies either a lack of viability of the vaccine or the existence of prior immunity. Immunity is not complete until 3 weeks after vaccination. As a further protective measure, removal of abrasive material from the environment is recommended but is not usually practicable. For the live-sheep export trade from Australia to the Middle East, sheep should be vac
cinated at least 3 weeks before shipment to allow immunity to develop.

Because the vaccines are live virus vaccines and the shed scabs contain live virus, routine vaccination against orf in flocks that have not experienced the disease is not recommended. Outbreaks have occurred from vaccine virus.

REFERENCES

ULCERATIVE DERMATOSIS OF SHEEP

Ulcervative dermatosis of sheep is an infectious disease characterized by the destruction of epidermal and subcutaneous tissues and the development of raw, granulating ulcers on the skin of the lips, nares, feet, legs, and external genital organs. The lesions on the lips occur between the lip and the nostril, those on the feet occur in the interdigital space and above the coronet, and the genital lesions occur on the glans and the external opening of the prepuce of rams and the vulva of ewes.

A virus, very similar to but antigenically different from the ecthyma virus, is the cause of the disease, which is likely to be confused with contagious ecthyma. However, the lesions are ulcerative and destructive, rather than proliferative as in ecthyma, and bleed easily. It is not highly infectious like blue-tongue or sheep pox, and the ‘lip-and-leg’ distribution of the lesions differentiates it from balanoposthitis of wethers, strawberry footrot (dermatophilosis), footrot, and interdigital abscess. The presence of lesions on the glans penis and their absence from mucosae, the typical ulcerative form of the lesion; the absence of pus; and the susceptibility of recovered animals to infection with ecthyma virus are diagnostic features of ulcerative dermatosis.

The typical morbidity rate is 15% to 20%, but up to 60% of a flock may be affected. Mortality is low if the sheep are in good condition and the lesions don’t get secondary bacterial infection or flystrike. Physical contact at breeding time seems to be the most probable method of spread.

The lip cutaneous form of this disease is very rare and possibly has disappeared since its original description, or is very uncommon. A clinically similar disease to the genital infection of ulcerative dermatosis, with balanoposthitis and vulvo-vaginitis, is associated with Mycoplasma mycoides.

FURTHER READING

POXVIRUS INFECTIONS IN HORSES (HORSEPOX, UASIN GISHU, VIRAL POPULAR DERMATITIS, EQUINE MOLLUSCUM CONTAGIOSUM)

Equids can be infected by horsepox virus or vaccinia virus. Infection is associated with classical horsepox, equine molluscum contagiosum, viral papular dermatitis, or Uasin Gishu disease and possibly a form of ‘greasy heel’ in horses and donkeys. Classical horsepox, caused by infection of horses by a specific poxvirus (horsepox virus, HSPV), was common before the twentieth century and was considered a rare, if not extinct, disease of horses until it was again identified in Brazil in 2010. The genome of HSPV has been determined and demonstrates that although it is closely related to vaccinia viruses, it contains additional genetic material that appears to confer some host specificity and pathogenicity. HSPV, with cowpox virus, was used for vaccination of humans against smallpox before introduction of use of vaccinia virus. Whereas most poxviruses are highly host adapted and do not cross species lines (e.g., variola virus causing smallpox in humans does not naturally infect animals), this is not the case with cowpox, horsepox, and vaccinia viruses, which can be zoonoses or anthroponoses. Widespread use of vaccinia virus live vaccines in humans was associated with a pox-like disease in horses. This disease has largely not occurred since the cessation of the smallpox vaccination program, but other poxvirus diseases in animals are reported, and infection appears to have the potential to be zoonotic for horsepox and cowpox viruses, or anthroponotic (reverse zoonosis) for vaccinia viruses.

The eradication of smallpox and the discontinuation of human vaccination in most countries were accompanied by a gradual reduction of the number of horse cases, although the disease is not eradicated, and infections involving cattle, horses and humans occur in Brazil. The virus isolated from horses (Pelotas 1 virus [P1V] and Pelotas 2 virus [P2V]) in Brazil is highly pathogenic in rabbits. The source of the vaccinia virus in these outbreaks has not been determined (e.g., wildlife, rodents).

Horses infected with the vaccinia virus used in human vaccine programs develop a transient and self-limiting disease characterized by pox-like lesions (papulopustular) in the mucous membranes of the mouth and in the skin of the lips and nose. Infection by particular strains of the vaccinia virus (P1V and P2V) in Brazil causes papules and vesicles progressing to proliferative and exudative lesions on the muzzle, external nares, and external and internal lips (Fig. 16-8). The vesicles erode, and the proliferative lesions progress to moist crusts and scars.

FURTHER READING

REFERENCES

The course of the disease varies between 10 days and 6 weeks. The disease is strongly suspected to be caused by a poxvirus. A febrile reaction, up to 40.2°C (104.5°F), precedes the appearance of skin lesions by about 24 hours. There is no histologic description. Recovery is usually complete and uncomplicated. The disease is clinically similar to molluscum contagiosum in horses associated with poxvirus. This disease has similar papular lesions, which are hypopigmented and covered by tufts of raised hair, but the disease has a long clinical course. Histologically, these lesions show proliferation of keratinocytes containing large intracytoplasmic inclusions, known as molluscum bodies, which are composed of numerous pox virions.

Differential diagnoses include greasy heel, vesicular stomatitis, viral papular dermatitis, molluscum contagiosum, and Uasin Gishu. See Tables 16-3 and 16-4.

There is no specific treatment. Local wound care is indicated. Because of the contagious nature of the disease, rigid isolation and hygiene in the handling of infected horses is essential. No vaccine is available.

**SWINEPOX**

**SYNOPSIS**

**Etiology** Swinepox virus.

**Epidemiology** Widespread sporadic disease that is generally benign with low morbidity and low mortality in older pigs. High case fatality in congenitally infected and very young sucking piglets. Transmitted mechanically and by the hog louse.

**Clinical findings** Characteristic pox lesions mainly on skin of head, legs, and belly.

**Clinical pathology** Demonstration of typical lesions by histology and virus by electron microscopy.

**Lesions** Typical pox lesions.

**Diagnostic confirmation** Demonstration of typical lesions by histology and virus by electron microscopy.

**Treatment** None.

**Control** Control of hog louse.

Swinepox virus causes a mild, acute disease of swine characterized by typical poxvirus lesions of the skin. There are no public health concerns.

**Note:** See also horsepox (Table 16-3).

### ETIOLOGY

The cause is swinepox virus, the sole member of the genus *Suipoxvirus* in the family Poxviridae.

### EPIDEMIOLOGY

**Occurrence**

Swinepox (pigpox) occurs worldwide where swine are raised and is more common in swine units where there is poor sanitation.

### Methods of Transmission

Transmission is not well understood. It is by contact transmission and mechanically by the pig louse (*Haematopinus suis*), and because these cannot always be found, it is suspected that possibly flies and other insects may also be involved. Young sucking pigs may have lesions on the face, with similar lesions on the udder of the sow, so there is evidence of spread by direct contact. Vertical transmission is also possible; there are reported cases of congenital infection. The virus can survive in scab material for several months and in dust and dried secretions.

### Animal Risk Factors

The virus infects only swine and can infect all ages, but clinical disease is most commonly seen in young piglets. It is usually a sporadic disease, with occasional outbreaks affecting a cluster of litters within a herd, and of short duration. Some or all pigs in a litter may show clinical signs. The disease may appear apparently spontaneously or may occur only in pigs brought into the contaminated environment of a herd in which the indigenous pigs are immune.

The incidence in individual herds may be high. Mortality is usually low except in very young piglets and congenitally affected piglets, where mortality rates can be high. Congenital infection presents with low morbidity but high case fatality. Older animals seem to suffer few ill-effects.

### PATHOGENESIS

The virus may enter the skin through preexisting skin lesions and then replicates in the keratinocytes of the stratum spinosum. It rarely affects other tissues. It can be isolated from the skin as soon as 3 days following intradermal inoculation. In field cases, the lesions progress through the classical phases of poxvirus infections but do not usually proceed past the pustular or vesicle stage. At this time there is rupture and the formation of scabs, which heal and drop off. Congenital infection is thought to occur when naive pregnant sows become infected and develop viremia with infection of the fetal membranes. Not all fetuses are born affected, and compartmentalization of placentas may restrict further uterine spread as occurs with parvovirus infections.

**CLINICAL FINDINGS**

The morbidity may be high in individual herds where young pigs are affected, but the mortality is usually very low. The incubation period may be from 4 to 14 days. Small 1- to 1.5-cm-diameter papules develop first and may pass through the pustular and vesicular stage very quickly with the formation of red–brown, round scabs. In neonatal pigs, the rupture of many vesicles at one time may...
cause wetting and scab formation over the cheeks, and conjunctivitis and keratitis are present in many affected animals. In most cases, the lesions are restricted to the belly and inside the upper limbs, but they may involve the back and sides and sometimes spread to the face. Lesions may coalesce. A slight febrile reaction may occur in the early stages in young animals, and in sucking pigs, deaths are observed. In adult pigs, detectable skin lesions are less well defined, restricted to the nonhaired softer skin areas, and frequently do not progress through the developmental stages to form scabs. Congenital swinepox is characterized by striking lesions present in piglets at birth, involving the skin and also commonly the tongue and hard palate. Affected piglets are born from healthy sows. Affected piglets may be stillborn or die within a few days after birth.

CLINICAL PATHOLOGY
The diagnosis is confirmed by examination of skin biopsies, which show hypodermic degeneration of the stratum spinosum keratinocytes. Focal superficial erosions, marked epidermal hyperplasia with acanthosis, ballooning of epidermal cells, and occasional large eosinophilic intracellular inclusion bodies are present on histologic examination. Hydric degeneration can also be seen in the outer sheaths of the hair follicles. There is no fluid accumulation between the keratinocytes. Necrosis may occur later. Inflammatory cells invade the underlying dermis. Electron microscopy can be used to detect the viral particles, and the virus can be cultured with at least seven passages. Crusts, containing antibodies but not at high enough concentration, or pustules are best for this. Pigs will develop virus-neutralizing and virus-precipitating antibodies but not at high enough levels to make antibody tests reliable. There is strong immunity in recovered animals.

TREATMENT
No specific treatment is available, and lesions cause so little concern to the pig, and heal so rapidly, that none is attempted.

CONTROL
Vaccination is not usually practiced, and control of the pig lice is the principal prophylactic measure attempted in most outbreaks.

Dermitomyces

RINGWORM

SYNOPSIS
Invasion of cutaneous keratinized epithelial cells and hair fibers by dermatophytes.

Etiology
Trichophyton, Microsporum spp. fungi.

Epidemiology
Carrier animals are the source; spread is via direct contact or contact with infected inanimate objects. Housed animals most susceptible.

Clinical signs
Circumscribed areas of hairless skin; thick gray crumbly crusts (cattle) or shiny, bald areas (horses); heavy pityriasis; common locations where infection likely to contact (e.g., neck, sides).

Clinical pathology
Spores and mycelia in skin scraping, or in culture.

Necropsy lesions
Mycelia identifiable in skin sections.

Diagnostic confirmation
Laboratory typing of fungus in scraping or tissue.

Treatment
Spontaneous recovery usual. Topical ointments such as Whitfield’s ointment, systemic griseofulvin. Vaccination widely used in European countries and supportive treatment.

ETIOLOGY
The associated fungi that grow on the hair, skin, or both are as follows:

- **Cattle**: Trichophyton verrucosum (most commonly), T. mentagrophytes, T. megninii, T. rubrum, T. mentagrophytes var. album, T. verrucosum var. discoides, Microsporum gypseum
- **Sheep**: T. verrucosum var. ochraceum, T. quinckeannum, T. mentagrophytes, M. gypseum ("club lamb fungus" in show lambs in the United States), Microsporum canis
- **Goat**: T. verrucosum
- **Horse**: T. equinum, including a dark variant able to perforate hair in vitro (T. equinum var. equinum), T. quinckeannum, T. mentagrophytes, T. verrucosum, Microsporum equinum (syn. M. canis), M. gypseum, Equidae species
- **Donkey**: T. mentagrophytes, T. verrucosum
- **Pig**: T. mentagrophytes, T. rubrum, T. verrucosum var. discoides, M. canis, Microsporum nanum

Uncommon dermatophytes also found in skin lesions in farm animals and horses include the following: M. gypseum and Keratinomyces albejoi in horses; Malassezia spp. yeasts causing superficial mycoses in immunocompromised horses; Scopulariopsis brevicaulis in cattle; M. nanum in adult pigs, in which it is most common and in which the lesions are often so mild as to go unnoticed by the farmer; and Alternaria alternata in horses, goats, pigs, sheep and cattle.

A rare but similar disease is tinea versicolor, a fungal dermatomycosis associated with Malassezia furfur (syn. Pityrosporum orbiculare) on the teats of goats. The lesions are circular, discrete, slightly thickened, and scaly at the edges, but not painful. They are characterized by an alteration in the color of the surrounding skin, either darker or lighter. The infection persists on a patient for at least a year and in a flock for a longer period. Hyperpigmentation is distinguishable in sections of the lesions.

EPIDEMIOLOGY
Occurrence, Source of Infection, and Transmission
Ringworm occurs in all animal species in all countries but more commonly where animals are accommodated in dense groups, especially indoors.

Direct contact with infected animals is the common method of spread of ringworm, but indirect contact with inanimate objects, particularly bedding, harnesses, grooming kits, and horse blankets, is probably more important. Spores can exist on the skin without causing lesions, and up to 20% of normal animals in an infected group will act as carriers and the lesions will go unnoticed by the farmer; and among premises and harnesses may remain infective for long periods because fungal spores remain viable for years if they are kept dry and cool. Moderate heat and desiccation destroy them.

A dermatophytosis in lambs in the United States, called club lamb fungus, affects lambs during lamb show season. Approximately one-third of families reported that children or owners involved in showing these lambs developed skin lesions consistent with dermatophytosis.

Ringworm in yearling horses can interfere with training, causing economic losses because of the isolation required to prevent spread of infection to other horses and humans and to decrease environmental contamination.

Risk Factors
Pathogen Factors
M. gypseum, K. allejoi, and M. nanum are soil saprophytes, and the reasons for their assumption of pathogenicity are not understood.
Environment and Host Factors
A high incidence of clinical cases in the winter and of spontaneous recovery in the spring is common, but outbreaks also occur during the summer months, so that close confinement and possibly nutrition seem to be more important in the spread of the disease than other environmental factors such as temperature and sunlight. Humidity is known to be important, with high humidity being conducive to multiplication of the fungus. In calf-rearing and vealing units the prevalence is greater in units that continuously add or remove calves from the stock; an "all-in-all-out" program is less conducive to spread of the disease.

Animal susceptibility is determined largely by immunologic status, and thus young animals are most susceptible.

Zoonotic Considerations and Economic Importance
Spread between species occurs readily, and in rural areas 80% of human ringworm may derive from animals. Trichophyton spp. infections are commonly contracted from horses and cattle and M. canis infections from dogs. Ringworm of animal origin affects adult humans and children, and diagnosis and treatment are often very difficult.

Injury to affected animals is of a minor nature, but sufficient damage to hides occurs to warrant some attempt at control of the disease.

PATHOGENESIS
Ringworm fungi chiefly attack keratinized tissues, particularly the stratum corneum and hair fibers, resulting in autolysis of the fiber structure, breaking off of the hair, and alopecia. Exudation from invaded epithelial layers, epithelial debris, and fungal hyphae produce the dry crusts that are characteristic of the disease. The lesions progress if suitable environmental conditions for mycelial growth exist, including a warm and humid atmosphere and a slightly alkaline pH of the skin. Ringworm fungi are all strict dermatophytes and require suitable environmental conditions for mycelial growth, including a warm and humid atmosphere and a slightly alkaline pH of the skin.

There is some experimental evidence that traumatic injury of the skin is an important factor for the development of ringworm lesions in calves. Different numbers of microconidia of T. verrucosum are required to induce ringworm depending on the degree of shearing of the hair and scarification of the skin. T. mentagrophytes secretes a small peptide (hemolysin) that is suspected to result in cell-membrane damage and facilitate infection of the skin.

Secondary bacterial invasion of hair follicles is common. The period after experimental infection before distinct lesions appear is about 4 weeks in calves, but considerably less in horses. Spontaneous recovery occurs in calves in 2 to 4 months, with the duration and severity of the disease often depending on the nutritional status of the host. A resistance to reinfection occurs after recovery from experimental or natural infection even though a local mycotic dermatitis may occur at the reinfection site. The immunity is specific to the fungal species concerned, and in horses immunity lasts up to 2 years.

CLINICAL FINDINGS
Cattle
The typical lesion is a heavy, gray–white crust raised perceptibly above the skin. The lesions are roughly circular and about 3 cm in diameter. In the early stages the surface below the crust is moist; in older lesions the scab becomes detached, and pityriasis and alopecia may be the only obvious abnormalities. Lesions are most commonly found on the neck, head, and perineum, but a general distribution over the entire body may occur, particularly in calves, and in severe cases the lesions may coalesce. Itching does not occur, and secondary acne is unusual.

Sheep
In sheep the lesions occur on the head and rarely in the fleeced areas, and although lesions usually disappear in 4 to 5 weeks, the disease may persist in the flock for some months. The lesions are discrete, round, nearly bald patches covered with a grayish crust. Similar lesions occur in goats, but they are distributed generally over all parts of the body. The exception to this description is a new ringworm associated with an unidentified Trichophyton that has appeared in sheep in the western U.S. states, plus Georgia and Kentucky, since 1989. Lesions occur extensively in fleeced areas and are characterized by shedding of the wool staple and exudation from the skin surface. Serious spread of the infection to human attendants occurs.

Horses
The lesions may be superficial or deep. Superficial infections are more common. Lesions resulting from T. equinum commence as round patches of raised hair and soreness of the lesions to touch. This stage is followed about 7 days later by matting of the hair, which becomes detached, leaving a bald, gray, shining area about 3 cm in diameter. Fine scabs appear, and recovery with regrowth of hair commences in 25 to 30 days. Heavier scabs and larger lesions are usually a result of rubbing by the harness. Lesions associated with M. gypseum are smaller, about 10 mm in diameter, and are manifested either by the development of thick crusts or, more generally, a diffuse moth-eaten appearance with desquamation and alopecia. Less commonly, deeper structures are infected through the hair follicles, causing small foci of inflammation and suppuration. A small scab forms over the follicle and the hair is lost, but extensive alopecia and crust formation do not occur. Some irritation and itching may be caused by this type. The distribution of lesions in the horse differs from that in cows, with lesions usually appearing first on the axillary girth area and spreading generally over the trunk and over the rump; lesions may spread to the neck, head, and limbs. Some cases are clinically impossible to differentiate from dermatophilosis.

Chromoblastomycoses is a sporadic, slow-developing chronic granulomatous fungal infection of skin following traumatic injury that has been reported occasionally in horses. Nodular granuloma-like nodules gradually appear that are clinically indistinguishable from habronemosis.

Brittle-tail syndrome of horses is a newly reported disease of horses in Hong Kong caused by a keratinolytic fungus, Equisetum hongkongense. Affected horses develop short, stumpy tails as a result of breakage of hairs in the dorsal layers of the tail. The disease is contagious, and environmental or animal reservoirs (apart from horses) are unknown.

Pigs
Ringworm is not common in pigs. Regular ringworm lesions in pigs develop as a centrifugally progressing ring of inflammation surrounding a scabby, alopecic center. The lesion produced by M. naum is different—there is no pruritus or alopecia and cutaneous reaction is minimal, but the centrifugal enlargement of each lesion may cause it to reach an enormous size. Superficial, dry,
brown crusts cover the affected area but are not obviously raised, except at the edges in some cases. The crusts are formed of flakes or dust composed of epithelial debris. Most lesions occur on the back and sides. Spontaneous recovery does not occur in adult pigs.

**CLINICAL PATHOLOGY**

Laboratory diagnosis depends on the demonstration of spores and mycelia in skin scrapings from the edge of the lesion and in culture. Skin scrapings should be made after decontaminating the skin with 70% ethyl alcohol, placing the scraping in a 10% solution of potassium hydroxide, and potentially adding lactophenol cotton blue before microscopic examination is performed. Spores are the diagnostic feature and appear as round or polygonal, highly refractive bodies in chains (Trichophyton spp.) or mosaics (Microsporum spp.) in hair follicles, in epithelial scales, and in or on the surface of hair fibers. A hair perforation test, which measures the capacity of a fungal isolate to perforate human hair fibers in the laboratory, is used in the differentiation of dermatophytic species. Culture can take 2 to 6 weeks to provide a diagnosis; consequently, a PCR test using the primer pair for chitin synthase 1 (CHS1) gene has been developed for use in horses. An ELISA for serodiagnosis has been developed for cattle, but it appears it will be used in the laboratory examination should be packed in envelopes because airtight jars and cans are not available or permitted in every country. Systemic treatment recommended for use in farm animals include the IV injection of sodium iodide (1 g/14 kg body weight) as a 10% solution repeated on several occasions, and, if the high cost of the treatment can be overlooked, the oral administration of griseofulvin has been empirically recommended at 7.5 to 10 mg/kg BW once daily, with no

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of ringworm depends on evidence of infectivity, the appearance of characteristic lesions, and the presence of fungal mycelia and spores. Diagnostic confirmation is by demonstration of fungal elements in a scraping or biopsy. The differential diagnosis list of ringworm, which may be confused with diseases with similar clinical profiles, follows.

**Cattle**

Mycotic dermatitis, which has tenacious scabs that cover a raw area of skin.

Inherited parakeratosis, characterized by tenacious thick crusts that respond quickly and completely to dietary supplementation with zinc.

Sarcoptic mange, in which mites can be demonstrated in scrapings; there is intense pruritus and a quick response to standard insecticides.

Psoroptic mange, identifiable by the presence of mites in scrapings, pruritus, occurrence in housed cattle, and the location of the lesions over the hindquarter.

**Horses**

Mycotic dermatitis, which is limited in its distribution to the back of the horse, and *Dermatonomus congolensis* can be cultured.

Queensland itch diagnosable on its occurrence only in summer, only along the back, and the associated intense pruritus.

Other equine dermatitides.

**Pigs**

Pityriasis rosea, in which no mites can be demonstrated, and the disease is limited to a particular age group.

Exudative epidermitis has extensive lesions with a characteristic greasy covering.

Tyrophilosis is self-limiting, associated with a new source of grain, and characterized by pruritus.

Sarcoptic mange, identifiable by the mites in scrapings, the intense pruritus, and the prompt response to treatment with insecticide.

**TREATMENT**

Many recorded cures are no doubt a result of strategic treatment just before spontaneous recovery, but treatment is widely practiced and recommended because it greatly reduces contamination of the environment by infected animals. Local or systemic treatments are used, the latter when lesions are widespread. Gloves and protective clothing should be worn when treating affected animals because of the potential for zoonotic spread. Administration of a live attenuated *T. verrucosum* vaccine to cattle with ringworm is effective in hastening the resolution of lesions. Vaccination with an inactivated lyophilized *T. verrucosum* vaccine twice at a 14-day interval has been reported to be an effective treatment in horses with multiple ringworm lesions.

**Local Application**

The crusts should be removed by scraping or brushing with a soft wire brush and burned; the selected medicament should be brushed on or rubbed in vigorously. Clipping of the hair may facilitate treatment application. Suitable topical applications include Whitfield’s ointment (a mixture containing 6% benzoic acid and 3% salicylic acid);[11,12] propicon and undecylenic acid ointments; povidone–iodine, thibendazole 1% to 5%, and captan ointments; ointments containing one of theazole compounds, such as imidazole, miconazole, or toconazole (1%),[13] or econazole (0.2%),[14] and a 10% ammoniated mercury ointment; propolis (a resinous substance collected by honeybees from plants);[15] homeopathic remedies;[16] burnt motor oil;[17] a 10% solution of povidone–iodine; 5% to 10% copper sulfate solution,[18,19] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadeca-methylene-1, 16-bis-isouquinolinium chloride (Tinevet), and Hexetidine (bis-1,3 beta-ethylhexyl-5 methyl-5-amino-hexahy-dropryrimidine) borotannic complex; and ivermectin (SC, 200 μg/kg BW).[20] The long list of potential treatments indicates the lack of a definitive, large-population, randomized clinical trial using objective measures of treatment efficacy and a negative control group. Whitfield’s ointment appears to have the strongest evidence of efficacy and is considered to have keratolytic, antimicrobial, and antifungal effects. Topical treatments are probably of greater value in the early stages of an outbreak when the lesions are small and few in number, and spontaneous resolution is likely in younger animals.

**Sprays, Washes**

When infection in a group is widespread, washes or sprays that can be applied over the entire body surface of all animals are used, although the efficacy of the preparations is less than that of ointments, and daily application for at least 5 days is required. Sprays have a big advantage if prophylactic treatment of all in-contact animals is recommended. Examples are agricultural Bordeaux mixture, 5% lime sulfur (20% w/v polysulfides diluted 1:20), captan (N-(trichloromethylthio)-cyclohex-4-ene-1, 2-dicarboxamide) 3%, N-trichloromethylthio-tetrahydrophthalimide; and captan ointments; ointments containing 10% solution of povidone–iodine; 5% to 10% copper sulfate solution;[18,19] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadeca-methylene-1, 16-bis-isouquinolinium chloride (Tinevet), and Hexetidine (bis-1,3 beta-ethylhexyl-5 methyl-5-amino-hexahydropryrimidine) borotannic complex; and ivermectin (SC, 200 μg/kg BW). The long list of potential treatments indicates the lack of a definitive, large-population, randomized clinical trial using objective measures of treatment efficacy and a negative control group. Whitfield’s ointment appears to have the strongest evidence of efficacy and is considered to have keratolytic, antimicrobial, and antifungal effects. Topical treatments are probably of greater value in the early stages of an outbreak when the lesions are small and few in number, and spontaneous resolution is likely in younger animals.

The crusts should be removed by scraping or brushing with a soft wire brush and burned; the selected medicament should be brushed on or rubbed in vigorously. Clipping of the hair may facilitate treatment application. Suitable topical applications include Whitfield’s ointment (a mixture containing 6% benzoic acid and 3% salicylic acid);[11,12] propicon and undecylenic acid ointments; povidone–iodine, thibendazole 1% to 5%, and captan ointments; ointments containing one of theazole compounds, such as imidazole, miconazole, or toconazole (1%),[13] or econazole (0.2%),[14] and a 10% ammoniated mercury ointment; propolis (a resinous substance collected by honeybees from plants);[15] homeopathic remedies;[16] burnt motor oil;[17] a 10% solution of povidone–iodine; 5% to 10% copper sulfate solution,[18,19] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadeca-

**Sprays, Washes**

When infection in a group is widespread, washes or sprays that can be applied over the entire body surface of all animals are used, although the efficacy of the preparations is less than that of ointments, and daily application for at least 5 days is required. Sprays have a big advantage if prophylactic treatment of all in-contact animals is recommended. Examples are agricultural Bordeaux mixture, 5% lime sulfur (20% w/v polysulfides diluted 1:20), captan (N-(trichloromethylthio)-cyclohex-4-ene-1, 2-dicarboxamide) 3%, N-trichloromethylthio-tetrahydrophthalimide; and captan ointments; ointments containing 10% solution of povidone–iodine; 5% to 10% copper sulfate solution;[18,19] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadeca-

**Local Application**

The crusts should be removed by scraping or brushing with a soft wire brush and burned; the selected medicament should be brushed on or rubbed in vigorously. Clipping of the hair may facilitate treatment application. Suitable topical applications include Whitfield’s ointment (a mixture containing 6% benzoic acid and 3% salicylic acid);[11,12] propicon and undecylenic acid ointments; povidone–iodine, thibendazole 1% to 5%, and captan ointments; ointments containing one of theazole compounds, such as imidazole, miconazole, or toconazole (1%),[13] or econazole (0.2%),[14] and a 10% ammoniated mercury ointment; propolis (a resinous substance collected by honeybees from plants);[15] homeopathic remedies;[16] burnt motor oil;[17] a 10% solution of povidone–iodine; 5% to 10% copper sulfate solution,[18,19] solutions of quaternary ammonium compounds (1:200 to 1:1000); solutions of 0.25% hexadeca-
strong evidence to support or refute this dosage protocol. Spontaneous recovery is common in individual animals within 90 days, and careful appraisal of results in clinical trials is necessary. Many farmers overtreat their animals with irritant preparations administered daily for long periods. A crusty dermatitis, or even a neoplastic acanthosis, may result.

**CONTROL**

**Hygiene**
Failure to control an outbreak of ringworm is usually a result of the widespread contamination of the environment before treatment is attempted. Isolation and treatment of infected animals; the provision of separate grooming tools, horse blankets, and feeding utensils; and disinfection of these items after use on affected animals are necessary if the disease is to be controlled. All grooming equipment should be carefully washed and treated with a solution of enilconazole or 1:10 dilution of household bleach. Cleaning and disinfection of stables with a commercial detergent or a strong solution (2.5% to 5%) of phenolic disinfectant, 5% lime sulfur, 5% formalin, 3% captan, or 5% sodium hypochlorite is advisable where practicable. Good results are also claimed for the disinfection of buildings with a spray containing 2.0% formaldehyde and 1.0% caustic soda. Sunlight and a low stocking rate provide very effective control measures, which is why ringworm occurs at a much lower incidence in suckling beef calves in pasture than dairy calves raised in group housing with no direct sunlight.

**Vaccination**
A vaccine developed in the former Soviet Union has achieved a great deal of success in preventing infection in cattle and horses in most countries of Europe and Scandinavia. The nonadjuvanted vaccine includes lyophilized microconidia and hyphal elements of a highly immunogenic, nonvirulent strain of *T. verrucosum*. Small injection-site skin lesions are present for a few weeks in vaccinated calves.17 Vaccination of all animals in the group is recommended, and isolation and treatment of infected animals and disinfection of premises and gear must be carried out at the same time.

The vaccine is almost totally without side effects except for very rare deaths as a result of anaphylaxis, apparently related to keeping reconstituted vaccine for too long a period. National vaccination campaigns have been successful in eradicating *T. verrucosum* from cattle herds.17

**Nutrition**
Although ringworm occurs in well-nourished and poorly fed animals, there does seem to be a tendency for the latter to become infected more readily and to develop more extensive lesions. Supplementation of the diet, particularly with vitamin A to young housed animals, should be encouraged as a preventive measure. The adequacy of dietary selenium and zinc intake should be determined.18

**REFERENCES**

**MUCORMYCOSIS**

Mucormycosis is a rare disease of humans, horses, cattle, and pigs caused by coenocytic fungi of the order Mucorales. *Lichtheinia corynbifera* (formerly *Abidia corymbifera*, *Mycoladus corymbiferus*) causes severe disease and death of horses, abscessation of lymph nodes in pigs, and mastitis and abortion in cattle.12 The disease is usually acute and progressive, and antemortem diagnosis is difficult. Clinical signs include fever, diarrhea, circling, convulsions, and acute death. Horses can have ulcerating skin lesions of the muzzle, nostrils, knees, and hocks, which can develop in animals that survive the acute disease. Necropsy examination reveals demarcated necrotic or hemorrhagic lesions in the respiratory and gastrointestinal mucosa, lungs, spleen, and brain. Thin-walled hyphae are visible in routine sections of tissue examined microscopically. There is no effective treatment or control. Zygomycotic lymphadenitis attributable to *Rhizomucor pusillus* or *Lichtheinia corymbifera* (formerly *Abidia corymbifera*) was detected in 0.04% of feedlot steers slaughtered in California. Lesions most commonly affected the mesenteric lymph nodes.7

**REFERENCES**

**MALASSEZIA SPP. DERMATITIS**

*Malassezia* spp., formerly known as *Pityrosporum*, is a genus of fungi. Dermatitis associated with *Malassezia* spp. is described in goats and horses. A number of species of *Malassezia*, including *M. furfur*, *M. obtusa*, *M. globosa*, *M. pachydermatis*, *M. restricta*, *M. sloffiae*, *M. symподiалis*, and *M. equina*, are present on normal and abnormal skin of horses.12 *Malassezia* spp. were cultured from 5 of 44 swabs and detected on microscopic examination in 40 of 44 swabs of preputial or mammary skin from 11 healthy horses, indicating the need for caution when ascribing etiologic importance to detection of this organism in samples of skin of horses with dermatitis.16

Lesions in a horse with alopecia areata included scaling and crusting dermatitis characterized histologically by mild to moderate hyperplasia, mild lymphocytic exocytosis, mild eosinophilic dermatitis, and diffuse parakeratosis with numerous budding yeasts. Alopecia areata might have predisposed the horse to infection, and disease caused by *Malassezia* spp., or the organism might have been an incidental finding.1 The putative disease in goats is not well characterized.15
Diseases
likely occurs throughout the world. The disease is reported to occur in Europe, India, Africa, and the United States and EPIDEMIOLOGY changes to a yeast phase when it enters a phase on living or decaying plant material spores. The organism survives in a mycelial dimorphic fungus that forms single-walled spores. The organism produces a local lesion containing large stercytes, such as Ethiopia, that have a dependent on use of equids as draft animals. In these communities, the disease has an adverse impact on affected equids beyond that caused by the lesions, because affected equids continue to be used as draft animals, because of lost utility of affected animals to owners, and because of the wider societal impact of the loss of availability of large numbers of draft animals. Income generated from providing a cart-horse service is often the sole source of income for families in developing countries, and the presence of the disease reduces the utility of the equid and therefore the income of the family.

SPOROTRICHOSIS

Sporotrichosis is a contagious disease of horses, dogs, cats, cattle, and humans characterized by the development of cutaneous nodules and ulcers on the limbs that may be accompanied by lymphangitis.

ETIOLOGY

Sporothrix schenckii (Sporothrix beurmanni, S. schenckii, S. equi) is a gram-positive fungus that forms single-walled spores. The organism survives in a mycelial dimorphic fungal organism in pus. Clinical characteristics of ulcerative lymphangitis, sporotrichiosis.

TREATMENT AND CONTROL

Systemic treatment with iodides (potassium iodide orally or sodium iodide IV) is the most effective treatment. Local application of tincture of iodine daily to ulcers may suffice in mild cases. Itraconazole might be effective.

Prophylactic treatment of all cuts and abrasions, isolation and treatment of clinical cases, and disinfection of bedding, harnesses, and gear will prevent spread of the disease in enzootic areas. Thorough washing of hands and arms with povidone iodine or chlorhexidine is recommended for humans handling infected animals or plant material.

REFERENCES

EPIDEMIOLOGY

The disease occurs as outbreaks in horses, donkeys, and mules in parts of Iran, Asia, India, northern Africa, and the Mediterranean littoral. Most outbreaks occur in spring and summer when large numbers of horses are gathered together for military or other purposes. The disease was detected 19% of cart horses in Ethiopia over an 18-month period, with the prevalence of the disease varying by geographic region from 0% to 39%. The disease was more prevalent in areas with higher mean temperature. The case-fatality rate is 10% to 15%, but the course is prolonged. Cattle and camels are rarely affected.

Fungal spores are carried from infected animals by direct contact or on bedding, grooming utensils, horse blankets, or harnesses, and gain entry through abrasions, usually on the lower limbs. A saprophytic stage in the soil has been suggested to account for the difficulty experienced in eradicating the disease. The organism has been isolated from the alimentary tract of biting flies, and they may play a role in the transmission of the disease.

Zoonotic Potential

Infection is reported in humans.

PATHOGENESIS

After gaining entry through wounds, the fungus invades subcutaneous tissue, sets up a local granuloma or ulcer, and spreads along the lymphatic vessels. The ocular form of the disease results from inoculation of the organism into the eye, likely by biting flies.

CLINICAL FINDINGS

The disease is primarily an ulcerating, suppurative, pyogranulomatous dermatitis, and, in most cases, lymphangitis. An ocular form of the disease is characterized by ulcerating conjunctivitis. Of 65 cases in cart mules in numbers of the yeast-like cells. The organism can be cultured on Sabouraud agar.

The disease is important in developing countries, such as Ethiopia, that have a dependence on use of equids as draft animals. In these communities, the disease has an

REFERENCES

The chronic nature of the disease.

Many animals are destroyed because of the disease. Spontaneous recovery occurs, usually after 12 months. Spontaneous recovery occurs.

Nodules that do not rupture are hairless. A spreading dermatitis involving the area and general swelling of the whole limb are common. The lesions are painless.

The lesions usually develop on the limbs, particularly around the hocks, but may also be present on the back, sides, neck, vulva, and scrotum. Occasionally lesions appear on the nasal mucosa just inside the nostrils and do not involve the nasal septum. Ocular involvement is manifested by keratitis and conjunctivitis. Sinusitis and pneumonia occur in other forms of the disease.

The disease is chronic, persisting for 3 to 12 months. Spontaneous recovery occurs, and immunity is solid after an attack, but many animals are destroyed because of the chronic nature of the disease.

**CLINICAL PATHOLOGY**

Gram-positive, yeast-like cells, with a characteristic double-walled capsule, are easily found in discharges. The organisms are located both extracellularly and intracellularly in giant cells and macrophages. The agent can be cultured on special media, but the fungus dies quickly in specimens unless these are collected in antibiotic solutions, refrigerated, and cultured promptly. The specimen should be collected into a solution containing 500 units/ml penicillin.

The mallein test is negative, but a sterile filtrate of a culture of *H. capsulatum* var. *farciminosum* has been used in a cutaneous sensitivity test, and several serologic tests, including a fluorescent antibody test, are available. Antibodies to *H. capsulatum* var. *farciminosum* are detectable in serum before or at the time of development of lesions.

**NECROPSY FINDINGS**

Lesions are usually confined to the skin, subcutaneous tissues, and lymph vessels and nodes. In some cases, granulomatous lesions may be found in the lungs, liver, and spleen. Histologically, the lesion is quite characteristic and consists of pyogranulomatous inflammation with fibroplasia. Langerhans giant cells are common. The presence of numerous organisms, some of which show budding, in both intra- and extracellular tissue sections stained with H&E, Periodic acid–Schiff reaction, and Gomori methenamine–silver stain is of diagnostic value.

**DIFFERENTIAL DIAGNOSIS**

See Table 16-4.

- Glanders (*Burkholderia mallei*)
- Ulcerative lymphangitis (*Corynebacterium pseudotuberculosis*)
- Sporotrichosis (*Sporothrix schenckii*)
- Histoplasmosis (*Histoplasma capsulatum*)

**TREATMENT AND CONTROL**

Many treatments have been tried, largely without success. Parenteral iodides have been reported as effective in some cases, as has amphotericin. Sodium iodide is administered as a 10% solution at a dose of 1 mL per 5 kg IV once weekly for 4 weeks. Amphotericin is administered at a dose of 0.2 mg/kg body weight every 48 hours for three treatments, but it might not be economically feasible for use in developing countries.

Outbreaks in uninfected areas are probably best controlled by *slaughter of affected animals*. In enzootic areas, severe outbreaks should be destroyed and less severe cases kept in strict quarantine while undergoing treatment; however, the high prevalence of the disease in some areas (39%) and economic importance to the horse owner of the animal continuing to work make this a difficult recommendation to enforce. All infected bedding, harnesses, and utensils should be destroyed or vigorously disinfected. Formalinized aluminum hydroxide adsorbed and heat-attenuated vaccines have been widely used, apparently with success.

**REFERENCES**

**ETIOLOGY**

The causes are fungi, including *Pythium insidiosum* (syn. *Hyphomycetes destruens*), Basidiobolus haptosporus (syn. *B. haptosporus* var. *minor*), Conidiobolus coronatus (syn. *Entomophthora coronata*), and *Rhinosporidium* spp. *Pseudoallescheria boydii* causes granulomatous lesions of the nasal cavity. *Alternaria alternata* causes small granulomatous lesions on the head of horses, especially young horses. *Scedosporium prolificans* has been associated with conjunctival lesions, arthritis, and osteomyelitis in horses. Unidentified fungi also cause lesions containing black-colored granules or grains, the so-called “black-grain mycetomas.”

Skin lesions in horses have been associated with infection by wide variety of fungi, including *Madurella mycetomatis*, *Carvularia verruculosa*, *Bipolaris speciferum*, *Cladosporium* spp., and *Exserohilum rostratum*. Nonpigmented fungi that cause localized fungal infections in horses include *P. boydii*, *Aspergillus versicolor*, *Alternaria tenuis*, and *Scedosporium apiospermum*. *B. haptosporus* is a terrestrial fungus that lives in decaying vegetation.

**Epidemiology**

Tropical and subtropical areas of the world. *Pythiosis* occurs during the wet time of the year, but there is no seasonal distribution for *B. haptosporus* or *C. coronatus*.

**Clinical signs**

All cause ulcerative granulomas. *P. insidiosum* causes lesions on the legs and ventral abdomen; *B. haptosporus* causes lesions on the side of the body, neck, and head; *C. coronatus* causes lesions in the oral, nasal, pharyngeal, and tracheal mucosa.

**Clinical pathology**

Agar gel double diffusion test and histologic examination and immunohistochemical staining of tissue sections.

**Lesions**

Ulcerative granulomas with sinus tracts containing yellow coagulated material.

**Diagnostic confirmation**

Histologic examination of tissue.

**Treatment**

Surgical excision. Sodium or potassium iodide. Vaccination.

**Control**

None.

**SYNOPSIS**

**Equine Phycomycosis (Swamp Cancer, Pithiosis, Hyphomycosis Destructus, Florida Horse Leech, Bursattee)**

**Etiology**

*Pythium insidiosum*, *Basidiobolus haptosporus*, or *Conidiobolus coronatus*
Pythiosis occurs mostly during the monsoon season in tropical areas, whereas infection by *B. haptosporus* and *C. coronatus* occurs year round. A survey in tropical northern Australia showed that granulomas of horses were caused by *P. insidiosum* in 77%, *B. haptosporus* in 18%, and *C. coronatus* in 5% of cases.

**Animal Risk Factors**

The fungi gain access to the subcutaneous tissues through wounds or other disruptions of the integrity of the skin or mucosa. A strong correlation between the occurrence of the lesions and frequent wetting and exposure to water is reported and is consistent with the concept of an aquatic life cycle and motile zoospores of *P. insidiosum*. There is no breed, age, or sex predilection. Multiple cases can occur in horses maintained in the same enclosure.

**Zoonotic Potential**

Many of these fungi cause disease in humans, for instance, *P. boydii* infection causes granulomas of the lower extremities of people in tropical regions and is referred to colloquially as Madura foot. However, there is no evidence of spread of infection from horses or other infected animals to humans, although appropriate caution should be exercised when handling infected tissues, especially by individuals with compromised immune function.

**PATHOGENESIS AND CLINICAL FINDINGS**

The life cycle of *P. insidiosum* involves colonization of leaves of aquatic plants where the organism undergoes sexual reproduction and produces sporangia. Motile zoospores, released from the sporangia, are attracted to plant and animal tissue to which they adhere. Zoospores are attracted to damaged tissue, on which they encyst and develop germ tubes. The hyphae invade tissue and produce the granulomatous reaction and ulceration. Ejected kunkers (necrotic material infected with hyphae) may produce sporangia. The large (20–cm), rapidly growing, circilar, fibrotic, ulcerative granulomas caused by *P. insidiosum* usually develop on the lower limbs, ventral abdomen, or thorax and contain yellow concretions in sinus tracts (leeches or kunkers). The lesions are pruritic and grow rapidly, often becoming greater than 20 cm in diameter in 1 month. *P. insidiosum* lesions may involve underlying bone, and osteomyelitis may be a common feature of chronic pythiosis of the lower limbs. *Pitygium* spp. infection of the small intestine causes eosinophilic enteritis and granuloma formation, resulting in colic and the need for surgical resection. Dissemination of infection from subcutaneous sites to the liver, lung, and spleen occurs and results in a progressive weight loss and eventual death.

*C. coronatus* causes lesions similar to, but smaller than, those of pythiosis. However, lesions are only on the nares, nasal passages, oral cavity, pharynx, or trachea. The lesions can be very slow growing and take 1 to 2 years to become invasive, whereas others grow rapidly. *P. boydii* causes granulomatous lesions of the nasal cavity in horses. *B. haptosporus* causes ulcerative, granulating lesions that have a hemorrhagic, edematous surface, in contrast to the fibrotic lesions caused by *Pitygium* spp., on the sides of the trunk, thorax, neck, and head. Lesions caused by *B. haptosporus* are pruritic.

*A. alternata* causes cutaneous nodules that are not painful or pruritic on the head of horses. The nodules may be solitary but usually multiple and slowly progressive. *S. prolificans* causes infection of musculo-skeletal structures, including joints and bone, usually secondary to puncture wounds or surgery. This organism causes disseminated lesions and a fatal disease in immunosuppressed humans.

**CLINICAL PATHOLOGY**

Culture of the causative fungus is a laborious task but is necessary to demonstrate presence of the organism, although PCR detection is becoming available and could replace culture as the definitive diagnostic test. A PCR test has been developed for the identification of *Pitygium* spp., and this test also is useful for the detection of *C. coronatus*. Horses infected with *P. insidiosum* have a positive reaction to an agar gel double-diffusion test, and complement fixation and intradermal hypersensitivity tests are also of diagnostic value.

Examination of a biopsy specimen is also of value, but care is needed to include a portion of necrotic tissue in which hyphae are most likely to be found. *P. boydii* is indistinguishable from *Aspergillus* spp. on microscopic examination of tissue. Immunohistochemical staining methods, using indirect peroxidase techniques, are of value in distinguishing *Pitygium* spp. from other fungi in swamp cancer lesions.

Necropsy examination of horses with disseminated pythiosis reveals small, firm, irregularly branched, yellow–white masses in the regional lymph nodes draining cutaneous lesions and in the liver, lungs and spleen. Histologically the masses are eosinophilic granulomas containing hyphal elements of *Pitygium* spp.

**TREATMENT**

The most efficacious treatment for pythiosis and conidiobolomycosis is excision, although recurrence is common (30%) with larger lesions. Laser ablation of the bed of the granuloma may reduce the rate of recurrence. Larger lesions are usually treated medically. Fungal lesions respond to treatment of sodium iodide (20 to 40 mg/kg BW IV, q 24 h, as a 20% solution), followed by oral administration of potassium iodide (10 to 40 mg/kg po q 24 h for 7 to 120 days). Potassium iodide can also be administered at a dose of 10 g/425 kg once daily, with the dose increasing by 2 g/day until the horse exhibits feed refusal or a dose of 20 g/day is achieved. Treatment should continue until signs of mycotic disease have resolved, which is often weeks to months. An alternative to potassium iodide is ethylene-diamine dihydroiodide (1.3 mg/kg, oral q 12 hours for up to 4 months and q 24 hours for up to 1 year). Iodination is a potential adverse effect of administration of sodium or potassium iodide, although this is rarely observed.

Amphotericin also gives good results as a systemic treatment (intravenously 0.4 mg/kg BW increasing to 1.5 mg/kg per day for 10 to 40 days) combined with local infiltration and after surgical excision in extensive lesions. Administration of amphotericin can be limited by its nephrotoxicity, which should be monitored during treatment. Itraconazole (3 mg/kg orally every 12 hours for 3 to 4 months) is effective in the treatment of *C. coronatus* infections of the nasal septum. Fluconazole (14 mg/kg oral loading dose followed by 5 mg/kg q 12 hours orally for 6 weeks) is effective in the treatment of nasal conidiobolomycosis in horses. The pharmacokinetics of fluconazole in horses have been determined, permitting rational dosing of this drug. Ketoconazole is not effective for the treatment of *C. coronatus* in horses.

Miconazole (5 grams of 2% solution) infused for 4 weeks into lesions in the nasal cavity, in combination with systemic administration of iodides, was effective in treatment of nasal lesions caused by *P. boydii*.

*S. prolificans* is resistant to commonly used antifungal drugs.

A vaccine composed of elements of *P. insidiosum* causes recovery or improvement in most cases. It also causes a severe reaction, sometimes a cold abscess, at the injection site. Other complications include osteitis and laminitis, which necessitate euthanasia.

**REFERENCES**

MADUROMYCOSIS

Maduromycosis is a skin disease of horses characterized by cutaneous granuloma caused by a variety of fungi, including Helminthosporium spiciferum, Brachycladium spiciferum, Curvularia geniculata, and Monosporum apiospermum. One or more lesions 1 to 2.5 cm in diameter appear anywhere on the skin but with a special frequency at the coronet. The incised lesion has a mottled appearance and drains pus containing the fungus.

Protozoal Diseases of the Skin

BESNOITIOSIS (ELEPHANT SKIN DISEASE)

SYNOPSIS

Etiology Intermediate host-speciﬁc tissue cysts of Besnoitia besnoiti, B. caprae, and B. bennetti.

Epidemiology Endemic disease in some tropical and subtropical areas, with high morbidity and low mortality. Rare disease elsewhere. Deﬁnitive host not known. Disease occurs in donkeys in the United States. Possible insect transmission of disease to cattle and goats.

Clinical ﬁndings Anasarca, alopecia, hyperpigmentation and scleroderma, and infertility.

Inspiratory dyspnea and loss of condition

Pin-point nodules (cysts) on the scleral conjunctiva and nasal, pharyngeal, and/or laryngeal mucosa.

Lesions Parasitic cysts in dermis, subcutaneous, and other fascia.

Diagnostic conﬁrmation Demonstration of bradyzoites in skin biopsy or scleral conjunctival scrapings.

Treatment and control Little information available.

Besnoitiosis is a parasitic disease of cattle, goats, horses, and certain wild animals. Infections in the chronic cystic stage can result in severe disease and/or production loss.1,5

ETIOLOGY

Besnoitia are cyst-forming coccidian (apicomplexan) parasites. The life cycle involves a deﬁnitive host and an intermediate host. There are seven classiﬁed species, of which three occur in domestic livestock. These are B. besnoiti in cattle, B. caprae in goats, and B. bennetti in horses, donkeys, and mules. The other four known Besnoitia species infect wildlife species. Cats are the deﬁnitive host for some Besnoitia infecting wildlife, but the deﬁnitive host(s) for the three domestic livestock species are unknown. Recent evidence suggests that B. besnoiti and B. caprae are the same genetically, that they also have the same bradyzoite ultrastructure, and that they may not be separate species.2,4

EPIDEMIOLOGY

Occurrence

Besnoitiosis of livestock animals occurs as outbreaks in some tropical and subtropical regions, and sporadically in other areas. In endemic areas, the disease can affect a large proportion of the herd and cause signiﬁcant economic loss.1-4 Bovine besnoitiosis is recorded in the African continent, southern Europe,4 South America, Israel, Asia, and the Russian Federation; caprine besnoitiosis in Kenya, Uganda, Iran, and Kazakhstan; and besnoitiosis is found in equids in Africa and has recently emerged in donkeys in the United States.5

Risk Factors

Besnoitia are relatively host speciﬁc. B. besnoiti infects cattle and in Africa also infects goats and wild ruminants. The Kenyan species of B. caprae does not infect cattle or sheep. The natural means of transmission is not known, but is presumed to be by ingestion of oocysts from the deﬁnitive host(s). Infection with B. besnoiti and B. caprae can be transmitted experimentally with endozoites and bradyzoites, and mechanically by infections or biting ﬂies. Outbreaks of disease in cattle or goats occur in ﬂy seasons, and it is postulated that biting insects may be important vectors. Transmission via semen from infected males is also suggested.

Economic Importance

B. besnoiti is an economically important parasite of cattle in Africa and Israel.2,3 Although mortality is generally low, morbidity can approach 10% in the chronic stages. There is a loss of condition, and the fertility of male cattle and goats can be signiﬁcantly impaired from chronic scrotal skin lesions. Skins have no value for tanning. Besnoitiosis in equids appears to have a rare occurrence, but there is evidence of an emergence in donkeys in the United States.4,5

PATHOGENESIS

Following infection of the intermediate host, the endozoites (tachyzoites) proliferate in macrophages, ﬁbroblasts, and endothelial cells, causing vasculitis and thrombosis, particularly in capillaries and small veins of the dermis, subcutis, and testes. They then mature to form bradyzoite cysts (cystozoites) within ﬁbroblasts. Replication is accompanied by cellular destruction and the release of inﬂammatory mediators, resulting in anorexia, lethargy, testicular degeneration, generalized edema of the skin, alopecia, and scleroderma.2,5 Besnoitia cysts form in high numbers in the dermis and subcutaneous tissue. Inspiratory dyspnea is associated with infection in the upper respiratory tract.

CLINICAL FINDINGS

Bovine Besnoitiosis

Typical signs occur in two stages: the acute anasarca stage associated with the proliferation of endozoites and the chronic scleroderma stage associated with cyst formation.2,4

Acute Stage

In the acute stage there is fever and an increase in pulse and respiratory rates; warm, painful swellings appear on the ventral aspects of the body, interfering with movement. There is also generalized edema of the skin. The superficial lymph nodes are swollen, diarrhea may occur, and pregnant cows may abort. Lacrimation and an increased nasal discharge are evident; small, whitish, and elevated macules may be observed on the conjunctiva and nasal mucosa. The nasal discharge is serous initially, but it becomes mucopurulent later and may contain blood.

Chronic Stage

As the disease becomes chronic, the skin becomes grossly thickened and corrugated, and there is alopecia. A severe dermatitis is present over most of the body surface. Affected bulls often become sterile for long periods, particularly if the scrotal skin is affected. Cystic stages of the Besnoitia have been found in vascular lesions in the testes of affected animals and may be a major contributor to the sterility. Cysts on the scleral conjunctiva are considered to be of particular diagnostic importance.

In endemic areas, the signs that attract clinical attention are alopecia and severely thickened and wrinkled skin, which is often thrown into folds around the neck, shoulder, and rump region and the carpal and tarsal areas. Small, subcutaneous, seed-like lumps can be palpated. In cattle, infections of the teat skin may result in lesions around the mouth in suckled calves. The case fatality rate can be ~10%, and the convalescence in survivors is protracted over a period of months.

Caprine Besnoitiosis

The acute stage is not commonly seen in goats; the disease presents like the chronic stage in cattle,1 with dyspnea and cutaneous lesions. The cutaneous lesion is a chronic dermatitis of the legs, particularly the carpal and tarsal regions, and the ventral surface of the abdomen. It varies from mild thickening with superficial scaling, to marked thickening with hyperpigmentation and a serous discharge. The hair is sparse.

Equid Besnoitiosis

The clinical signs are similar for different species of equids (horses and donkeys).4,5 Animals may show exercise intolerance, nasal discharge, and inspiratory dyspnea.
Skin lesions, like those in cattle and goats, are present on the ventral abdomen and legs or the whole body surface. Pin-point white nodules can be seen on the nares and sclera, and by endoscopy on the soft palate, pharynx, and/or larynx.

**CLINICAL PATHOLOGY**

There is little information on hematology and blood chemistry. Hypergammaglobulinemia has been reported in one horse. Cysts containing a number of banana- or spindle-shaped zoites can be detected in scrapings or sections of skin or scleral conjunctival scrapings. Ear-tip biopsies are commonly used in surveys of goats, and many infected animals show no clinical signs of infection. Serum antibodies to Besnoitia spp. can be detected using an indirect immunofluorescence technique or ELISA, but such tests likely have inadequate sensitivity and specificity.

**NECROPSY FINDINGS**

At necropsy, apart from any lesions detected upon clinical examination, animals that die in the acute stage of disease usually have widespread petechiae and ecchymoses in the subcutis and edema in the lymph nodes and in the testis in males. In the chronic stage, small white granules (the size of sugar granules) may be found in multiple muscles, intermuscular fascia, and tendons, particularly in the limbs, neck, and nasal mucosa. Parasite stages are evident in lesions upon histologic examination, and they are found in endothelial cells and the intima of blood vessels, often associated with necrosis and a mild inflammatory reaction.

**DIAGNOSTIC CONFIRMATION**

The most efficient and cost-effective method of diagnosis of clinical disease is the demonstration of Besnoitia bradyzoites in skin biopsy smears or scleral conjunctival scrapings. PCR-based techniques might also be used.

**TREATMENT AND CONTROL**

There is little information on treatment. Clinical cure of a donkey with a 9-month history of chronic skin disease is reported following prolonged oral administration of trimethoprim–sulfamethoxazole.1 Animals should receive supportive therapy and be treated symptomatically for enteritis or dermatitis. A vaccine containing Besnoitia besnoiti, grown on tissue culture and originally isolated from blue wildebeest, has been used to vaccinate cattle. A durable immunity to the clinical form of the disease was reported, but low-level subclinical infection did occur.

**SUMMER SORES IN HORSES (HABRONEMOSIS)**

**SYNOPSIS**

**Etiology** Three nematode species, Habronema muscae, H. majus (syn. H. microstoma), and Draschia megastoma, infect the horse.

**Epidemiology** Larvae from eggs in the feces are ingested by fly larvae; adult flies deposit infective larvae on skin.

**Signs** Larvae deposited in wounds or in eye cause local inflammation and the development of extensive granulation tissue.

**Clinical pathology** Larvae may be found in skin scrapings, biopsies, or discharge; marked local eosinophilia.

**Lesions** Adult D. megastoma cause tumorlike lesions in stomach; other species cause a catarrhal enteritis.

**Diagnostic confirmation** Gastric form: eggs difficult to find in feces; cutaneous form: demonstration of larvae, eosinophils in biopsy or scraping.

**Treatment** Ivermectin.

**Control** Protect horses from flies; treat all skin wounds promptly.

**ETIOLOGY**

The various forms of cutaneous habronomosis, with local names such as “summer sores,” “swamp cancer,” and “bursattee,” involve three nematode species, Habronema muscae, Habronema majus (syn. microstoma), and Draschia megastoma, the adults of which infest the stomach of horses.

**LIFE CYCLE**

Habronema spp. adults are larger (1 to 2.5 cm long) than those of D. megastoma (1.25 cm). The life cycles are indirect; all species use flies as their intermediate hosts. D. muscae and D. megastoma mainly use the housefly (Musca domestica) but can use other muscid species, whereas H. majus usually passes through the stable fly (Stomoxyx calcitrans), although Haematobia irritans exigua, Sarcoptophaga melanura, and the housefly can also be used. The thin-walled larvated eggs hatch in the manure and are ingested by maggots, in which they develop. The infective form is reached at about the time the adult fly emerges from the puparium. Horses become infected by swallowing dead flies with feed or water, or, alternatively, infective larvae may pass through the proboscis of the fly when it is feeding on the lips or on wounds. Larvae that are swallowed reach maturity in the stomach, whereas those deposited in wounds cause cutaneous habronomosis. Stray larvae may be found anywhere throughout the body but occasionally massive invasion of the lungs is seen.

**EPIDEMIOLOGY**

Habronema and Draschia have a worldwide distribution. They are of importance only in warmer climates, where they are commonly found, especially in wetter areas where the intermediate hosts are common. Elsewhere they tend to be a sporadic nuisance. Gastric granulomas and most cutaneous lesions appear to be associated with D. megastoma, although typical cutaneous lesions do occur naturally and have been produced experimentally by the cutaneous implantation of H. majus or H. muscae larvae. The latter, however, only cause a transitory reaction. Horses of all ages are susceptible, but the disease is most common in adults.

**PATHOGENESIS**

Two types of gastric habronomosis occur. The more serious is associated with D. megastoma. Larvae invade the gastric mucosa and cause the development of large granulomatous masses that later fibrose. These tumors contain adult worms and have a central orifice through which eggs and larvae escape into the lumen. In many horses, the lesions cause only a mild chronic gastritis. In rare cases perforation occurs and is followed by a local peritonitis, which may involve the intestine, causing constriction, or the spleen, causing abscesses. H. majus and H. muscae do not cause tumors but penetrate the stomach glands and cause a catarrhal gastritis with the production of a thick tenacious mucus. Heavy burdens may cause ulceration. In donkeys, hyperoxemia, edema, erosions, and ulcers in addition to parasitic lesions have been observed.

In cutaneous and conjunctival habronomosis, Habronema spp. larvae deposited in wounds cause local inflammation and the development of extensive granulation tissue. Secondary bacterial or mycotic invasions may occur. In the eye, similar lesions form on the inner canthus, the nictitating membrane, or the eyelid. These can cause diffuse lacrimation and other signs of local irritation.

**CLINICAL FINDINGS**

Gastric habronomosis does not usually provoke clinical signs, but affected animals may, on occasion, have a poor coat and a
variable appetite. Large tumors may cause pyloric obstruction and gastric distension. When perforation occurs, there is depression, a fever of 39.5° to 40.5° C (103° to 105° F), and pain and heat on the left side just behind the costal arch. Mild to moderate colic may be evidenced when intestinal stenosis is present. If the spleen is involved, there is marked anemia and a gross increase in the total leukocyte count with a shift to the left.

**Cutaneous habronemosis** is manifested by the appearance of lesions on those parts of the body where skin wounds or excoriations are most likely to occur and where the horse cannot easily displace the vector flies. Thus they are most common on the face below the medial canthus of the eye and on the midline of the abdomen, extending in males onto the prepuce and penis. Less commonly, lesions may be found on the legs and withers, but those occurring in the region of the fetlocks and coronary band are especially serious. The cutaneous lesions commence as small papules with eroded, scab-covered centers. Development is rapid, and individual lesions may increase to 30 mm in diameter in a few months. The center is depressed and composed of coarse, red granulation tissue covered with a grayish necrotic membrane, and the edges are raised and thickened. Although the lesions do not usually heal spontaneously, they may regress in colder weather and recur the following summer. There is little discharge. The sores are unsightly, are inconvenient, and cause some irritation.

In **conjunctival habronemosis**, lesions on the nictitating membrane may be as large as 5 mm in diameter. The conjunctivitis is manifested by small, yellow, necrotic masses about 1 mm in diameter, accompanied by soreness and lacrimation, which do not respond to standard treatments for bacterial conjunctivitis.

**CLINICAL PATHOLOGY**

Diagnosis is difficult in the gastric form of the disease because the eggs and larvae are not easy to find in the feces. Biopsy of a cutaneous lesion reveals connective tissue containing small, yellow, caseous areas up to 5 mm in diameter. Larvae may be found in skin scrapings or biopsies, and ocular lesions can be found in the conjunctival sac or discharge. A marked local eosinophilia occurs.

**NECROPSY FINDINGS**

Tumor-like lesions of *D. megastoma* bulge into the lumen of the stomach and may reach the size of a golf ball. Adult *Habronema* are stout worms, but their presence is often masked by a thick, tenacious layer of mucus. This is on the glandular part of the stomach and often close to the margo plicatus.

**Granulomatous lesions** may be found in all the sites mentioned in the description of clinical signs, and although varying in size, they are of essentially the same composition as described earlier under “Biopsy.” Horses that have had the cutaneous form of the disease may have small nodules in the parenchyma of the lung. These are hard and yellowish and contain inspissated pus and larvae.

**DIAGNOSTIC CONFIRMATION**

A biopsy will confirm clinical diagnosis of the cutaneous and conjunctival forms of the condition. Experimentally, PCR assays targeting the application of the Internal transcribed spacer 2 (ITS2) of ribosomal DNA for specific identification of *Habronema* spp. in feces and biopsies have been developed.6,7

**DIFFERENTIAL DIAGNOSIS**

The gastric form of habronemosis is difficult to differentiate from infection with stomach bot (*Gasterophilus* larvae or *Trichastrogylys* axei). These parasites often coexist in the same animal. Cutaneous habronemosis must be distinguished from:

- Fungal granulomata associated with *Hyphomyces destructus*
- Overgrowth of granulation tissue following a wound
- Equine sarcoids

**TREATMENT**

Few anthelmintics have been adequately tested against *Habronema* spp. and *D. megastoma*. Ivermectin 0.2 mg/kg will remove these species from the stomach with a single SC treatment,8,9 but a second dose is sometimes necessary to promote healing in cutaneous lesions. Moxidectin (0.4 mg/kg) is active against adult *Habronema muscae*. Fenbendazole used at 10 mg/kg PO once daily for 5 days is reported to have high efficiency against *D. megastoma* and possibly *Habronema* spp.

**CONTROL**

Interruption of the life cycle by careful disposal of horse manure and control of the fly population are obvious measures. In enzootic areas all skin wounds and excoriations should be treated promptly to promote healing and protect them against flies.

**FURTHER READING**

**REFERENCES**

**RHABDITIS DERMATITIS**

*Pelodera* is a subgenus of the soil nematode *Rhabditis*. Dermatitis associated with the larvae of *P. strongyloides* is rare. It is recorded most commonly in the dog, but outbreaks have been observed in cattle, sheep, and horses. It has also been an incidental finding in other skin diseases associated with poor husbandry practices. Alopecia is marked, particularly on the neck and flanks. In moderate cases the skin on affected areas is thickened, wrinkled, and scurfy, and some pustules are present on the ventral abdomen and udder. Pustules are up to 1 cm in diameter and contain thick, yellow caseous material and worms. There is marked irritation and, in severe cases, affected areas are swollen and raw and exude serum.

*Pelodera strongyloides* is a free-living soil nematode found particularly in decaying leaf mold and similar material. When warm-blooded animals lie on its habitat for prolonged periods, it takes the opportunity to invade the skin. Thus infestation is encouraged by housing animals on warm, wet bedding. Under favorable conditions, the disease may spread rapidly. In these circumstances the lesions occur most commonly where the skin contacts the bedding. The nematodes are easily detected in skin scrapings or biopsy specimens and in samples of the bedding, preferably taken from the top few centimeters in the pen.

**CONTROL MEASURES** include the regular removal of soiled bedding and steps to ensure that the litter is kept dry. Spontaneous recovery usually occurs if these precautions are taken, but local application of a parasiticide and symptomatic therapy will speed recovery.

**REFERENCE**

**ONCHOCERCIASIS (WORM NODULE DISEASE)**

*Onchocerca* spp. are filamentous, thread-like nematodes found mostly as convoluted masses in fibrous tissues. They vary in length; those of the horse are 15 to 18 cm long, whereas bovine species may be as long as 75 cm. They are filarial worms, and the females produce motile embryos (microfilariae). These congregate in the skin and subcutaneous tissues at the favored feeding site of their intermediate host. Each *Onchocerca*...
species uses a particular biting fly, usually a species of Culicoides (midge) or Simulium (blackfly). Transmission takes place when infective larvae that develop in the fly are deposited on the skin of their host at a subsequent feed.

Infestation by adult worms is often symptomless, and prevalence tends to increase with age. Relatively nonpathogenic species of widespread occurrence in cattle include *O. gutturosa* in the gastrosplenic ligament, whereas *O. lienalis* and *O. gutturosa* are widespread occurrence in cattle include *O. g. nubecula* and *O. g. culicoides* in the peritoneal cavity. Horses often harbor *O. cervicis* in the ligamentum nuchae and *O. reticulata* around the flexor tendons. In horses *O. cervicis* can cause recurrent fluid-filled masses over a period of years. Relatively nonpathogenic species of widespread occurrence in cattle include *O. g. nubecula* and *O. g. culicoides* in the peritoneal cavity. Horses often harbor *O. cervicis* in the ligamentum nuchae and *O. reticulata* around the flexor tendons. In horses *O. cervicis* can cause recurrent fluid-filled masses over a period of years.

**Diseases**

**PARAFILARIOSIS**

Horses in Europe, particularly eastern Europe, China, South America, and North Africa, are sometimes infected with *Parafilaria multipapillosa*, a 3- to 6-cm-long nematode. The female lives in a nodule in the skin, which it pierces to lay eggs on the surface. The subcutaneous nodules ulcerate, bleed, heal, and disappear spontaneously. The hemorrhagic exudate from the lesion attracts bloodsucking flies such as *Haematobia*, which ingest the eggs and act as the intermediate host. The condition is relatively benign, occurring in the spring, summer, and autumn. Many nodules may occur on a horse, but although unsightly, they do little harm unless they interfere with harness straps.

Similar lesions in cattle are associated with *P. bovicola*, which is endemic in eastern and some western European countries, *O. armillata*, most commonly on the scrotum and udder. Other species may be more pathogenic, such as *O. cervicalis*, which lives in the aorta of cattle, buffalo, and goats in India and Iran.

**Loses caused by adult worms** are slight, although *O. gibsoni* in cattle causes unsightly lesions and rejection of beef carcases from the high-class meat trade. The characteristic nodules of *O. gibsoni* are usually freely movable and consist of fibrous tissue canalized by the long body of the worms. With *O. armillata*, the inner wall of the aorta may be corrugated and swollen. In horses, new infections with *O. reticulata* may cause swelling of the suspensory ligament and a hot edematous swelling of the posterior part of the cannon that persists for 3 to 4 weeks. After the swelling subsides, the suspensory ligament remains thickened, and small calcified nodules may be palpated. Affected animals are lame while the area is edematous and swollen, but many recover when the swelling disappears. *O. cervicis* causes fibrotic, caseous, and calcified lesions in the ligamentum nuchae, but clinical signs are not seen. The conditions known as “poll evil” and “fungous wounds” are no longer thought to be associated with this parasite.

**Microfilariae** may sometimes be damaging. Those of *O. cervicis*, for example, are occasionally observed in the cornea of horses, but the proposed causal relationship with periodic ophthalmitis is no longer thought to be valid. They can, however, induce hypersensitivity reactions in the skin of some individuals. Lesions are characterized by alopecia, scaliness, and pruritus, particularly along the ventral abdomen. They may extend between the forelegs and backlegs to include the thigh, and in severe cases they may extend up the lower abdominal wall. Some horses have lesions on the face, neck, or thorax. The lesions may be confused with those associated with horn-fly feeding, but these are more likely to include crusting and ulcerating dermatitis. In onchocercosis, microfilariae are not detectable in the bloodstream but may be found in skin biopsies.

**Control** of the intermediate hosts is virtually impossible, but valuable horses prone to hypersensitivity to *O. cervicis* microfilariae can be partially protected by housing at night because most *Culicoides* species feed during twilight hours and/or at night. The use of insect repellents and avoidance, if possible, of grazing areas where the insects are likely to be in large numbers will also be beneficial. There is no specific treatment for the adult worms. A novel approach has been the experimental use of tetracycline to eliminate *O. ochengi* by killing the symbiotic bacterium Wolbachia, which is found in many, but not all, filarial species.

An experimental multivalent subunit vaccine based on recombinant proteins of *O. volvulus* has shown partial protection against patent *O. ochengi* infection in cattle. Experimental treatment with three doses of 4 mg/kg melarsomine hydrochloride in aqeous solution by slow IV injection on alternate days has been shown to be macrofilaricidal in cattle with *O. ochengi* infection. Oral ivermectin 0.2 mg/kg or moxidectin 0.4 mg/kg can be used to eliminate microfilariae in horses, but recurrence of microfilariae and lesions has been observed even after repeated treatment with ivermectin. About 10% of treated horses develop an edematous reaction within 24 hours. This is usually restricted to the area of the lesion, but some may develop a puritic ventral edema.

**DISEASES**

**PARAFILARIOSIS**

Horses in Europe, particularly eastern Europe, China, South America, and North Africa, are sometimes infected with *Parafilaria multipapillosa*, a 3- to 6-cm-long nematode. The female lives in a nodule in the skin, which it pierces to lay eggs on the surface. The subcutaneous nodules ulcerate, bleed, heal, and disappear spontaneously. The hemorrhagic exudate from the lesion attracts bloodsucking flies such as *Haematobia*, which ingest the eggs and act as the intermediate host. The condition is relatively benign, occurring in the spring, summer, and autumn. Many nodules may occur on a horse, but although unsightly, they do little harm unless they interfere with harness straps.

Similar lesions in cattle are associated with *P. bovicola*, which is endemic in eastern and some western European countries, *India* the Philippines, Japan, and South Africa. It has recently become established in Canada, Ireland, and Sweden, where it spread at a rate of 50 km/year. Muscid flies, for example, *Musca autumnalis* in Sweden and Belgium, act as the intermediate host, and the prepatent period in cattle is 7 to 9 months. The condition is seen mostly in late winter, spring, and summer and causes widespread economic losses as a result of carcass trimming and hide damage. The majority of lesions are superficial and localized, but sometimes they cover the whole carcass. In such cases intermuscular lesions will be found within the fascia of adjacent muscles. Subperitoneal, abdominal, subpleural, and thoracic lesions may also occur and cause condemnation of the whole carcass. *Suifilaria suis* causes similar lesions in the pig in South Africa.

Clinical signs are restricted to the presence of bleeding points, and a diagnosis may be made by examining a smear of the exudate microscopically for larvated eggs.
Ivermectin markedly reduces the area of the lesions and the mass of affected tissue. A control program for *P. bovicola* using ivermectin has been evaluated. Blood spots were dramatically reduced, but transmission was not stopped. Nitroxynil 20 mg/kg twice at 72-hour intervals is effective in reducing the number and area of lesions, but care must be taken to ensure accuracy of dosing or toxic signs of drug overdose may be seen. Topical levamisole may also be effective.

**REFERENCES**

**STEPHANOFOILARIASIS**

*Stephanofilaria* spp. are very small (up to 8 mm) filarial nematodes living in cysts at the base of hair follicles. They are associated with subcutaneous tissue lesions in cattle and buffalo. There are a number of species, including *S. dedoesi* (synonyms *S. assamenis*, *S. kaeli*, and *S. okinawaensis*), which provokes a dermatitis (“cascado”) affecting the eyes, neck, withers, shoulders, and dewlap in cattle in parts of Asia, in addition to “hum-psore” in India, leg sores on cattle in Malaysia, and muzzle and teat lesions in Japan. *S. zaheeri* causes “earsore” in India, and *S. stilesi* is responsible for dermatitis of the ventral abdomen in parts of the United States and Russia. A similar species in Queensland, Australia, affects the head, neck, dewlap, and sternum. *S. boomkeri* has recently been described in pigs in Africa. The adult worms release microfilariae that later develop into flies that feed on the sores. The vector for *S. dedoesi* is *Musca conduens*, whereas the horn fly *Haematobia irritans* is the intermediate host for *S. stilesi* in the United States. The Australian species is probably spread by the buffalo fly, *Haematobia irritans exigua*.

**Cutaneous stephanofilariosis** starts with small papules that later coalesce to produce lesions varying from 3 to 15 cm in diameter. They are an extreme irritant, and evidence of rubbing is present. Part but not all of the hair is lost, and dried exudate forms a thick, crumbly scab that may crack to expose blood-stained fluid. Skin scrapings taken from beneath the scab may reveal worm fragments. If healing occurs, the scab disappears, leaving a scar. Infection does not affect growth rate, and treatment and control are required only in stud cattle in which lesions are esthetically undesirable.

**TREATMENT**

Levamisole (7.5 mg/kg PO) (R-2)

Ivermectin is an effective microfilaricide in buffaloes and reduces the number of adult worms. Oral levamisole 7.5 mg/kg once or twice at 3- to 4-week intervals is reported to be effective. Ointments containing insecticides may aid control. The Asian species require a preexisting wound for infection to take place. Simple wound prevention and treatment would therefore reduce the risk of disease in this region.

**BLOW-FLY STRIKE OF SHEEP**

Blow-fly strike ("strike") is a very important cause of production and economic loss in most countries where large numbers of sheep are kept. In bad years many sheep may die (up to 30% of a flock), and the expense of controlling the flies and failure of wool to grow after recovery may be a serious cost, both for individual farmers and the overall industry. For example, in Australia the annual cost of blow-fly control and production losses in 2014 was estimated at around A$170 million. Merino sheep, especially those with heavy skin wrinkles and fecal soiling, are by far the most susceptible breed.
ETIOLOGY

Despite there being a large number of species capable of causing the disease, there are two species that initiate most strikes and are of primary concern: Lucilia cuprina and Lucilia sericata. Locations of typical species are as follows:

- **Australia**: L. cuprina, L. sericata (secondary flies include Calliphora stygia, Calliphora novica, Calliphora aegur, Calliphora hilli, Calliphora albifrontalis, Chrysomyia rufitarsi, and Chrysomyia varipes)
- **New Zealand**: L. sericata, L. cuprina (C. stygia)
- **Great Britain and northern Europe**: L. sericata (secondary flies include Calliphora erythrocephala, Calliphora vomitoria, and Phormia terra-novae)
- **North America**: Phormia regina, P. terra-novae

LIFE CYCLE AND EPIDEMIOLOGY

The primary agents of flystrike are obligate parasites. *L. cuprina* is overwhelmingly important in the initiation of strike in sheep from Australia and South Africa. *L. cuprina* was confirmed to be present in New Zealand in 1988, and flystrike from this species is now a major disease in that country. In northern Europe the primary agent of flystrike is *L. sericata*, although there are some other minor species that have been reared from struck sheep.

The incidence varies widely, depending largely on the climate, with warm, humid weather being most conducive to a high incidence. In summer-rainfall areas flystrike may be seen most of the year, being limited only by dry winter conditions. In winter-rainfall areas it is usually too cold in the winter and too dry in the summer for outbreaks to occur. Under these conditions abnormally heavy summer or autumn rains may be necessary before an outbreak will occur.

The Fly Population

Primary flies are of particular importance because they initiate the strike and provide suitable conditions for subsequent invasion by secondary flies. These latter flies are not of economic importance but may infest wool matted with dried exudate or feed on necrotic tissue surrounding a healing strike. In warm areas, pupal development may continue throughout the year, but as soil temperatures fall an increasing number of larvae fail to pupate, and larvae may overwinter until the following spring. Adult flies emerge in the spring, and after one to two breeding cycles, numbers increase to a peak in summer. Numbers may remain high if climatic conditions are suitable, with adequate moisture being of prime importance, but fall dramatically in hot and dry conditions during the summer. An increase in numbers may occur again in the autumn.

All adult flies require carbohydrate and water, but females require protein for ovarian development. The flies are attracted to sheep that have undergone prolonged wetting such that bacterial growth and decomposition of the skin occurs. The association of breech strike with diarrhea and urine staining, and body strike with fleece rot, mycotic dermatitis, and footrot, is related to the excessive moisture deposited on the skin or to the production of serous exudates. Fleece-rot-affected wool with *Pseudomonas aeruginosa* has been shown to stimulate oviposition.

*L. cuprina* deposit eggs in batches of up to 300, the actual number depending on the fly’s size and its ability to locate sufficient protein for egg development. Similarly, *L. sericata* deposit eggs in batches of approximately 200.

The average female longevity in the field in Australia is about 2 weeks, and females rarely live long enough to mature more than two or three batches of eggs. In the United Kingdom, mean female longevity is shorter at 5 days.

The eggs hatch in 12 to 24 hours, and the first instars feed on protein-rich serous exudate that has been provoked by bacterial damage or some other irritation. Larval mouth hooks and enzymes present in the saliva and excreta will further digestion of the skin. Large groups of larvae, particularly second and third instars, further damage of the skin, which extends the lesion and ensures a continuing supply of food. The second and third instars are 6 to 12 mm long, thick, and yellow and white in color, and they move actively. Larvae reach maturity after approximately 72 hours. They leave the feeding lesion, fall to the ground, wander briefly, and then burrow into the earth to pupate. The length of the life cycle is highly temperature dependent; it can be completed in as little as 8 days but may require up to 6 weeks in temperate regions such as the United Kingdom. Egg and larval stages are highly susceptible to desiccation, and mortality will be high if the relative humidity in the fleece falls below 60%. In temperate climates when the temperature declines in autumn, wandering larvae that have left the sheep will burrow into the ground but cease development, thereby overwintering as arrested mature larvae.

A few generations of primary flies are necessary before numbers are high enough to cause severe outbreaks, and so warm, humid weather must persist for a reasonable time before severe outbreaks occur. The incidence of body strike increases with the increase in the number of gravid flies and is positively correlated with rainfall, cloud cover, and rate of pasture growth. Other primary flies are not as effective as *L. cuprina* in initiating a strike, and in Australia and South Africa 85% to 90% of all primary strikes are a result of *L. cuprina*. Larvae of primary flies, other than *L. cuprina*, and secondary flies develop in carrion or in rotting vegetation, and their main role is to invade sheep and extend the primary strike. *Ch. rufitarsis* is the most important secondary fly in Australia. It requires higher temperatures than the other flies, is found later in the season, and is the first to disappear as temperatures fall.

Detailed population models have been developed for the strike by *Lucilia* spp. in Australia and northern Europe, and both have been used to predict onset of flystrike in sheep populations. The latter model has been extensively validated and is sufficiently accurate to establish an early warning system for alerting producers of the impending onset of flystrike, and hence the optimum time for prophylactic treatment.

Distribution of flystrike in flocks is highly aggregated, with a small number of sheep having high numbers of larvae in lesions, a moderate number of sheep with low numbers of larvae, and the majority of sheep being unstruck. In part this is a result of the attractiveness of already-struck sheep to ovipositing flies, although other factors, such as innate attractiveness to flies, shown by the propensity of some sheep to be restruck within the same fly season, also play a role.

Susceptibility of Sheep

By far the most common site for flystrike is the breech, resulting from soiling and excretion by soft feces and the urine of ewes. Lush pasture, parasitic gastroenteritis, and fleece length are predisposing factors, but individual sheep are predisposed because of their breech conformation. Excessive wrinkling of the skin on the back of the thighs and perineum, a narrow perineum and crutch, and an excessively long or short tail favor continuous soiling of the area and encourage “breech strike” or “tail strike.”

“Body strike” occurs along the dorsum of the body, especially in young sheep in wet seasons when fleece rot or dermatophilosis is common. Less common sites for infestation are around the prepuce (“pizzle strike”) and
on the dorsum of the head when there is excessive folding of the skin ("poll strike"). Sheep grazing on tall, dense pasture are commonly affected by body strike because wet plants keep the fleece on the lower part of the body wet. Footrot lesions and wounds, especially castration incisions, docking wounds, and head wounds on rams caused by fighting, are also likely to provide good sites for blow-fly strike. Young sheep are more susceptible.

**PATHOGENESIS**

The first instars feed on the exudate produced by the bacterial infection on the skin, but the larvae also produce excretory/secretory enzymes that may cause some skin degradation after egg hatch and provide soluble molecules on which the first instars can feed. Later instars can cause severe skin damage when feeding. Larvae may also migrate from the original area of strike, along the surface of skin, to establish additional focal lesions.

Many primary strikes remain small and are unnoticed by the farmer. Such “covert” strikes may outnumber obvious strikes and are important as a source of future generations of flies. Once the initial strike is made, the site becomes suitable for the secondary flies, which invade and extend the lesion. The effects of strike include toxemia as a result of absorption of toxic products of tissue decomposition, loss of skin and subsequent fluid loss, and secondary bacterial invasion.

**CLINICAL FINDINGS**

Individual sheep may be struck at any time provided they are in a susceptible condition. Massive outbreaks tend to be confined to periods of humid, warm weather and are therefore in temperate areas usually limited in length to relatively short periods of 2 to 3 weeks, but in subtropical areas characterized by summer rainfall, severe strikes may occur over many months.

The clinical effects of blow-fly strike vary with the site affected, but all struck sheep have a basic pattern of behavior caused by the irritation of the larvae. The sheep are restless, moving about from place to place with their heads held close to the ground, and they become anorexic. They tend to bite or kick at the struck area and continually wriggle their tails.

If the area is large, there is an obvious odor, and the wool can be seen to be slightly lifted above the normal surrounding wool. The affected wool is moist and usually brown in color, although in wet seasons (when fleece rot is prevalent) other colors may be evident. In very early cases, the maggots may still be in pockets in the wool and not yet in contact with the skin. When they have reached the skin, it is inflamed and then ulcerated, and the maggots begin burrowing into the subcutaneous tissue.

Three days after the primary oviposition feed intake is reduced, rectal temperature rises to about 42°C (108°F), and pulse and respiratory rates increase. There is a reduction of feed intake and loss of body weight, and some sheep may die. The wool may be too hot to handle as a result of the inflammation caused by the mass of maggots that can be seen when the wool over the strike is opened. When primary strikes are invaded by secondary flies, particularly C. rufifacies, the affected area is extended, and the maggots may burrow deeply into the tissues. Affected sheep may lose their fleece over the affected area (Fig. 16-9) and may suffer a break in the remaining fleece. Tracts of discolored wool may lead to other affected areas of skin. As the struck area extends, a scab forms over the center, the wool falls out, and the maggots are active only at the periphery.

**CLINICAL PATHOLOGY AND NECROPSY FINDINGS**

A clinical examination is all that is necessary to make the diagnosis, but identification of the flies responsible may be important if epidemiology is being considered. Identification of larvae should be carried out by a specialist. Molecular techniques for accurate identification are available but are a specialized research technique rather than routine diagnostic tool. Preservation of the larval stages is critical to these techniques, and larvae should be rapidly frozen or preserved in 70% ethanol. Fly trapping may not correlate with larval findings because not all flies are attracted equally by the commonly used baits.

**DIFFERENTIAL DIAGNOSIS**

Attention will be drawn to affected sheep by their foot stamping, tail twitching, and biting at the affected part. Affected sheep can easily be diagnosed by finding the moist, malodorous, maggot-infested area. Many covert strikes may be present without producing clinical signs. Predisposing diseases such as footrot, wound infections, dermatophilosis, and diarrhea resulting from parasitic gastroenteritis are usually easily detected, and fleece rot is indicated by matting of the wool and discoloration.

**TREATMENT**

Removal of wool from the surrounding area removes most of the maggots, and applying a dressing prevents reinfection of the wound. Dressings containing cyromazine, spinosad, ivermectin, or an organophosphate such as diazinon, tetrachlorfenvinphos, or propetamophos (if permitted), are the most commonly used. Cyromazine is an insect growth regulator, and thus live larvae will be seen in the fleece for some days after treatment. Thus other chemicals need to be included in a dressing if immediate killing of larvae is desirable. Ivermectin at 0.3 mg/kg is highly effective in killing all larval stages, and no resistance has yet been reported. However, resistance to organophosphates is widespread in Australia; many products do not kill all the resistant larvae, with some performing poorly even against susceptible larvae. Preventing reinfections is important, and thus application of the larvicide to the wool surrounding the treated area is essential.
CONTROL
In Australia, practical control of breech strike of Merino sheep in extensive farming areas has relied on the use of the Mules operation, which removes breech wrinkle and extends the bare areas around the perineum and tail. This has been integrated with other strategies to reduce the susceptibility of Merino sheep to strike, such as effective worm control to reduce diarrhea, and hence contamination of the perineal region with feces ("breech soiling"), correct tail length, strategic timing of crutching and shearing, and timely application of insecticides (an integrated pest management approach).17

Control of strike in other situations is based on insecticidal treatment and treatment of wounds as they occur.

Under conditions of extensive sheep rearing, such as occur in Australia, New Zealand, and South Africa, and where climatic conditions are conducive to the development of the disease, the control of blow-fly strike is a major challenge. An extensive literature on the subject is available, so only a summary is given here.

Control programs can be thought of as having three components: reduction in fly numbers (mainly by strategic application of insecticide and fly trapping), prediction of risk periods (to most appropriately time activities such as crutching, shearing, or the application of insecticide), and reduction in susceptibility of sheep (mulesing of Merinos, genetic selection for plain breeches and/or reduced breech cover; control of predisposing factors, particularly diarrhea and fleece rot).

Reduction of Fly Numbers
Reducing the fly population has been of limited value because there are usually enough flies present to strike all susceptible sheep if suitable conditions are present. Nevertheless, if the primary fly responsible for initiating strikes can be controlled, the buildup of primary flies and involvement and importance of secondary flies is greatly reduced. Measures include early insecticide treatment, just before or after the first generation of primary flies emerge in areas that have a seasonal pattern of fly emergence; trapping of flies; early treatment of clinical cases; and the proper disposal of carcasses and wool waste. Biological control by the use of insects parasitizing blow flies has been proposed but has yet to be exploited.

A weather-driven model of flystrike risk in southeastern Australia predicted that strategic early treatment would reduce the number of treatments and have a positive cost-benefit outcome in high-risk areas where preventive treatments were routinely given, but there was less benefit for low-risk areas because treatments were not needed every year.8 A large-scale field study comparing early strategic treatment of unmulesed Merino sheep with mulesed ones not given an insecticide found a similar prevalence of strike in both groups and concluded that this was a potential medium-term strategy for the control of strike in unmulesed Merinos in this area.19

Trapping, provided the traps are carefully tended and satisfactory baits are used, can reduce the number of blow flies. However, the benefits in reducing the prevalence of strike are mixed. The use of a trap designed specifically for *L. sericata*, the primary fly in the United Kingdom, reduced strikes by 55%.20 However, despite reducing the numbers of *L. cuprina* by 60% to 80%, the use of a trap specific for this species (*LuciTrap™*) has not consistently reduced the prevalence of strikes in Australia or South Africa.21 In addition, it is expensive and logistically difficult to use these traps in large flocks at the suggested distribution of 1 trap per 100 sheep. Nevertheless, trapping can still be useful to indicate the presence and abundance of blow flies and the most appropriate time to apply a strategic early treatment.11

It is also important to identify clinically affected sheep, particularly those affected early in the season, and to treat these infestations. If early-season strikes are not treated, they can propagate a larger second and third generation of flies on a farm, given that *L. cuprina* doesn’t travel large distances. Thus large farms breed most of their own flies, and so outbreaks of strike will be potentially more problematic later in the season. When affected areas are clipped, the clippings should be treated with a suitable dressing to kill the larvae, then burned or buried.

Control by genetic manipulation of the fly offers some promise for long-term control, but this strategy has yet to be exploited with either *L. cuprina* or *L. sericata*. For example, reduced fertility in male flies and lethal mutants, such as flies that will be blind under field conditions and die, have been reported. The sequencing of the draft genome of *L. cuprina* may facilitate these and other developments, such as exploring genetic mechanisms of insecticide resistance, the design of novel insecticides, and other strategies.12

Prediction of Risk Periods
Flystrike results from a complex interaction between fly abundance and sheep susceptibility, both of which are directly related to weather, geography, and animal husbandry. Predictive models incorporating climatic and production components have been developed in the United Kingdom and are used to give producers warning of impending flystrike.3 In Australia, models have been incorporated into tools on an advisory website for farmers and advisers (Flyboss), enabling them to compare management systems for flystrike risk.

Outbreaks of breech strike will occur if sheep have diarrhea or if ewes have urine wetting of the breech area because their tails are docked too short or too long. If an outbreak is routinely expected, such as during spring in a winter- or uniform-rainfall area, removal of breech wool by crutching or shearing, and/or the prophylactic application of insecticides, will largely eliminate or reduce the severity of strike. Crutching is routinely carried out before lambing or an expected increase in fly numbers and provides protection from strike for around 6 weeks in crossbreeds and mulesed Merinos but for a shorter period in unmulesed Merinos. It has a significant cost as a result of the labor and loss of wool involved, and thus many sheep farmers use prophylactic treatment with an insecticide.

Sporadic cases of body strike may occur in sheep at any time and cannot always be prevented, but if environmental circumstances conducive to high fly populations and high susceptibility of sheep are recognized, then short-term prophylactic measures can be taken. Warm, showery weather extending over several weeks allows several generations to be completed and sufficient flies to be available to cause an outbreak of strike. Once sufficient flies are present, an outbreak of flystrike may occur whenever the sheep become susceptible. Warm, humid weather, rain over 2 to 3 days, or grazing in long and wet grass may provide suitable conditions for the sheep to become susceptible to body strike. Sheep with poor physical conformation (e.g., high shoulder blades), fleece that is yellow with high suint and low wax content, and a wool staple structure more prone to wetting (pointed, thin staples that are less tightly packed) are most susceptible. The time of year when shearing is carried out also exerts a strong influence on the frequency and severity of outbreaks of body strike because the staple length when sheep are wetted determines the degree of wetting and rapidity of drying. It also influences susceptibility to breech strike, with a longer staple length usually facilitating a greater accumulation of feces ("dag").

Treatment and Prevention
Prophylactic treatment with insecticide has been a major part of blow-fly control for many years, and surveys in countries with significant sheep populations show that up to 90% of farmers in high-risk areas routinely treat their sheep. Currently available chemicals include the insect growth regulators (dicyclanil and cyromazine), macrocyclic lactones (ivermectin), and spinosyn (spinosad). Organophosphate chemicals have also been heavily used, but resistance is widespread, and thus the period of protection is reduced to as little as 3 to 5 weeks. There is also increasing concern over their environmental effects and occupational health and safety, and thus their use is restricted or prohibited in many jurisdictions. Resistance by *L. cuprina* to cyromazine has been detected in Australia, but application of this chemical at the recommended
concentration is still effective in preventing reinfestations.13 Depending on the formulation used, the insect growth regulators can provide 10 to 12 (cyromazine) and 18 to 24 (dicyclanil) weeks of protection, and can be applied by high-volume jetting (cyromazine) or a low-dose spray (both). Their action is specific to dip- teran larvae, although they inhibit chitin synthesis and thus larvae do not die until they molt.

The methods of application include dipping, jetting, and tip spraying. However, dipping requires specialized equipment, has higher labor costs, and is much slower and thus is not recommended unless lice are also present. Jetting is recommended for breech strike, and if the jetting piece is combed through the wool from the poll to the rump with the solution at high pressure (500 to 900 KPa), this method will also prevent body strike.

**Reducing the Susceptibility of Sheep**

The primary method for reducing the susceptibility of Merino sheep to breech strike has been the modified Mules and tail-strip operation.14 Mulesing, originally developed to remove the wrinkled region of the breech, has been modified by incorporating pain relief to address concerns regarding animal welfare, which must be balanced against the effects of strike. Although still permitted by codes of practice in Australia, the technique remains controversial because of ongoing opposition from animal welfare activists and concern over production losses. The latter accrue following a significant growth setback when lambs are mulesed at a young age (6 to 10 weeks old), often leading to reduced weaning weights and higher mortality rates after weaning. The protection gained by mulesing surpasses that afforded by breeding and is immediate and permanent.

The Mules operation is often supplemented by a tail-strip operation, whereby a thin strip of woolled skin is removed from each side of the tail. This stretches the bare skin over much of the tail, reducing fecal and urinary contamination. Unfortunately, some contractors dock tails too short, leaving a “butted” tail that the sheep is unable to elevate when defecating, thereby increasing the degree of breech soiling (dag). When butted tails are combined with mulesing, there is often a high prevalence of squamous-cell carcinoma of the vulva. Consequently, docking tails to the correct length (tip of the vulva in ewes) and leaving a V-shaped flap of wool bearing skin on the tip of the tail is important.

Alternatives to mulesing have been developed and investigated in an ongoing research program funded by Australian woolgrowers.15 These methods include plastic breech clips, applied to the breech of lambs at a similar age to mulesing, and the intradermal injection of compounds, such as sodium lauryl sulfate, into the breech area.16 Unfortunately, to date no alternative has produced the degree of breech modification achieved by mulesing, nor have they significantly reduced the prevalence or risk of breech strike compared with unmulesed sheep. For example, in a field study involving over 6000 sheep there was a significant reduction in the breech wound lesions of hoggets and ewes that had clips applied as lambs, but these changes were only a fraction of the reduction seen in mulesed sheep. Compared with mulesed sheep, the clipped ones had from 3 to 27 times the risk of breech strike as hoggets, and 2 to 8 times the risk of strike as maiden ewes.19 Consequently, selective breeding to reduce the susceptibility of Merino sheep to breech strike is being recommended. This possibility was first noted in the 1930s, when sheep with certain breech characteristics were found to have a far higher risk of breech strike, whereas others were relatively immune.14 However, these investigations were discontinued as a result of the effectiveness and widespread adoption of mulesing, plus the development of highly effective insecticides. Genetic selection offers cumulative and permanent chan ges, although not total reduction in risk. Several risk factors for breech strike were identified in a large-scale study in western Australia involving over 2800 unmulesed lambs sired by 49 rams.20 The most important of these were breech soiling (dag), urine staining, and breech “cover” (the reverse of bare area), which had genetic correlations with breech strike of 0.64 to 0.81, 0.54, and 0.32, respectively. Breech wrinkling was not identified as a risk factor because these were a plain-bodied genotype of sheep. However, a similar study of typical wrinkly fine-woollen Merinos in a summer-rainfall area confirmed a strong relationship between breech strike and breech wrinkling.15 This research has been summarized and published on an open-access website called Flyboss.16 A similar genetic and phenotypic relationship of breech soiling with breech strike has been demonstrated for New Zealand Romney sheep and in the United Kingdom.20

Other good management practices are essential to prevention of flystrike. These include management of gastrointestinal nematodes to prevent diarrhea (“scouring”), docking of tails to the correct length, and crutching before a risk period (typically before lambing with ewes) to reduce breech soiling that predisposes animals to breech strike. Pizzle strike can be dramatically reduced or eliminated by the use of testosterone implants to prevent posthitis (“pizzle rot”), and “ringing” (shearing of the pizzle area) provides 6 to 8 weeks of protection from strike. Pizzle dropping (the surgical separa- tion of the preputial sheath from the belly) also provides good protection. However, treated sheep can be more difficult to shear, and it will no longer be an approved practice when draft Australian animal welfare standards are endorsed.21 Fleece rot occurs most commonly on the withers of sheep, and the conformation that allows accumulation of moisture and the development of fleece rot and flystrike is heritable, so sheep with these faults should be culled. Although control is mainly centered on management, the application of an insecticide may be needed when weather conditions are particularly suitable for body strike, such as summer storms.

**SCRWESWORM (COCHLIOMYIA HOMINIVORAX AND CHRYSOMYIA BEZZIANA)**

Cutaneous myiasis associated with the screwworm maggots has been a cause of great financial loss in livestock in the western hemisphere, Africa, and Asia. Deaths may be heavy in groups of livestock that are at range and seen infrequently.

**SYNOPSIS**

Etiology Cochliomyia hominivorax in the New World (New World screwworm) and...
ETIOLOGY

Larvae of the flies C. hominivorax and C. bezziana cause myiasis or "screwworm disease" of animals. The flies are typically blowflies, C. hominivorax (New World screwworm), which is blue–green with an orange head, or C. bezziana (Old World screwworm), which is of similar coloring. C. hominivorax occurs in the Americas, and C. bezziana occurs in the Persian Gulf, Africa, and Asia. The occurrence of C. bezziana in Papua New Guinea provides a constant threat to livestock on the Australian mainland. A similar fly is Callitroga (Cochliomyia) macellaria, which is not a true "screw-fly" in that the larvae feed only on carrion or necrotic tissues.

EPIDEMIOLOGY

The screwworm maggots are obligatory parasites with no host specificity. Thus all domestic and wild mammals, marsupials, and birds are potential hosts. Females are attracted to fresh wounds, where they will oviposit. The navel of a newborn animal is a favored site, but fresh accidental or surgical wounds, such as those produced by castration, docking, and dehorning, are readily infested. Wounds that have already been infested are markedly attractive to the flies because of their odor. In bad seasons the flies will lay eggs on minor wounds such as areas of excoriation, tick bites, running eyes, peeling brands, and on the perineum soiled by vaginal and uterine discharges in animals that have recently given birth. Injury is not necessarily a prerequisite for screwworm strike in sheep, which can be struck in the intact infraorbital fossa and vulva. Wool loss and tenderness may occur, and the remaining fleece may be stained.

The development of the fly is favored by hot, humid weather. The optimum temperature range for C. bezziana is 20° to 30°C (68° to 86°F). Below this temperature, the flies become sluggish, and at 10°C (50°F) and below the flies will not move. Temperatures above 30°C (86°F) can be tolerated, provided shade is available. C. hominivorax is active all year in areas where temperatures exceed 16°C (61°F) and disperses rapidly from these areas as the temperature increases in the neighboring colder areas. The disease can be spread either by migration of flies or their carriage in livestock ships or commercial aircraft, by shipment of infested cattle or other livestock, and by movement of affected wildlife. The mean distance that C. bezziana can travel and deposit eggs is 11 km. The maximum distance is 100 km, but long distances are probably wind assisted. In the new environment the flies may die out if the climate is unsuitable or persist to set up a new enzootic area. Persistence of the fly in an area may depend on persistence in wildlife or in neglected domestic animals, although the latter do not usually survive unattended for more than about 2 weeks.

In many enzootic areas it is common for the fly to persist in neighboring warmer areas during winter, returning to its normal summer habitat as the temperature rises. This pattern is exemplified by the introduction of screwworms into the southeastern United States in 1933 where they had not previously occurred. The flies died out in most areas in winter but persisted in southern Florida. In succeeding summers migrations of flies northward caused outbreaks. The disease has since been eradicated from the area.

The disease is of importance in tropical and subtropical areas of Africa, Asia, North and South America, the Caribbean islands, Mexico, American states bordering on Mexico, and especially Central America. The prevalence of the fly in enzootic areas places severe restriction on the times when prophylactic surgical operations can be carried out.

The potential worldwide geographic distribution and abundance of C. bezziana has been assessed using a computer program. The differences in the observed global distribution and the potential predicted distribution indicate the areas at risk of colonization.

LIFE CYCLE

The screwworm flies have a typical fly life cycle with eggs, three larval instars, and a pupal stage. Females lay 150 to 500 white eggs in shingle-like clusters at the edges of fresh wounds. Larvae hatch in about 12 hours and penetrate the tissues surrounding the wound. The larvae preferentially feed on fresh, living tissue, which is digested by regurgitation of a wide variety of salivary enzymes. Oviposition by other screwworm flies is encouraged by the presence of larvae already in the wound. The larvae feed as a group and at their time of maturation will have created a deep lesion 10 to 12 cm in diameter. Larval development is complete in 5 to 7 days, after which they leave the wound and fall to the ground. These mature third instars burrow into the upper soil layers and pupate. On the ground, pupal development is highly temperature dependent, requiring from 3 to 60 days. Emerging flies commence egg-laying in about 1 week, having completed the life cycle, under optimum environmental conditions, in less than 3 weeks. There may be 15 or more generations per year.

The temperature sensitivity of the pupal stage, which is unable to survive freezing for more than short periods, limits the distribution of this parasite. As with all flies, pupal development is highly temperature regulated. The screwworm pupal development is inhibited at soil temperatures below 15°C (60°F). Temperatures below this point for more than 2 months cause death of the pupa. Thus the occurrence of the disease is limited to warm climates. Pupae are also affected by the moisture content of the soil. The emergence of adults is reduced when the moisture content is more than 50%, whereas temporary floods can drown pupae.

PATHOGENESIS

Following invasion of the wound a cavernous lesion is formed, characterized by progressive liquefaction, necrosis, and hemorrhage. Anemia and decreased total serum protein result from hemorrhage into the wound. Secondary bacterial infection, toxemia, and fluid loss contribute to the death of the animal. Surviving calves frequently develop infectious polyarthritis.

CLINICAL FINDINGS

The young larvae invade the nearby healthy tissues vigorously and do not feed on necrotic superficial tissue. A profuse brownish exudate, composed of larval excreta and host fluids, pours from the wound, and an objectionable odor is apparent. This is highly attractive to other flies, and multiple infestations of a single wound may occur within a few days. The resulting tissue damage may be so extensive that the animal is virtually eaten alive. Affected animals show irritation in the early phase of the infestation and by day 3 show pyrexia. Animals do not feed but wander about restlessly, seeking shade and shelter.
CLINICAL PATHOLOGY
It is imperative to differentiate screwworm infestation from infestation with other fly larvae. The appearance and smell of the wound are significant, but careful examination of the larvae is necessary to confirm the diagnosis. Mature larvae are 1 to 2 cm long and pink in color; they are pointed anteriorly and blunt posteriorly; two dark lines are visible reaching from the blunt posterior to the middle of the body, and they have rows of dark fine spines on the anterior part of each segment. Specimens forwarded to a laboratory for identification should be preserved in 70% alcohol.

NECROPSY FINDINGS
Superficial examination of infested wounds is usually sufficient to indicate the cause of death.

DIFFERENTIAL DIAGNOSIS
The presence of maggots in the wound is usually apparent. It is important to differentiate them from blow-fly larvae as described previously.

TREATMENT
Affected wounds should be treated with a dressing containing an efficient larvicide and preferably an antiseptic. The larvicide should be capable of persisting in the wound for some time to prevent reinfection. An ointment or gel base is preferred so that as much of the active ingredient as possible is left in the site. It should be liberally and vigorously applied with a paint brush to ensure that larvae in the depths of the wound are destroyed. To avoid reinfection in extensive lesions or in bad seasons, the treatment should be repeated twice weekly.

Thirteen acaricides, commonly used for *Boophilus microplus* control, have been tested against *C. bezziana* larvae. Although they are not sufficiently active to use as a primary treatment, their continued use for tick control would reduce screwworm populations. Ivermectin 200 mcg/kg given subcutaneously kills all *C. bezziana* larvae up to 2 days old and many older larvae. It provides residual protection for 16 to 20 days. Bull calves treated with ivermectin at the time of castration were completely protected against strike. A preliminary study showed that closantel at 15 mg/kg body weight was effective, with a residual protection of 8 to 15 days. Doramectin 200 mcg/kg subcutaneously caused complete expulsion of *C. hominivorax* larvae within 8 days. Prophylactic use of ivermectin and doramectin significantly reduced occurrence of screwworm strike in cattle. Fipronil had a prophylactic effect, reducing occurrence of screwworm infestations in cattle and providing efficacious treatment in those that did become infested.

CONTROL
In an enzootic area the incidence of the disease can be kept at a low level by the general institution of measures designed to break the life cycle of the fly. Surgical procedures should be postponed where possible until cold weather. In the warm months all wounds, including shearing cuts, must be immediately dressed with one of the preparations described under “Treatment.” All range animals should be inspected twice weekly and affected animals treated promptly. Infestation of fresh navels is common, and newborn animals should be treated prophylactically. If possible, the breeding program should be arranged so that parturition occurs in the cool months. The routine use of ivermectin for internal parasite control provides protection for about 2 weeks.

In the United States, the Caribbean, and Central America, an eradication program has been successfully carried out against *C. hominivorax* using the sterile insect technique (SIT). Huge numbers of pupae are mass reared on semiartificial media and exposed to the sterilizing effects of cobalt 60. The resulting sterile male flies are released over large areas, primarily by aerial drops, where they compete with wild males for available females, which mate only once. *C. hominivorax* has now been eliminated from the United States, the Caribbean, and all of Central America, up to the Darien Gap in Panama. *C. hominivorax* appeared in Libya in 1988, apparently with a load of sheep transported from South America, but has been eradicated using sterile male flies from the United States.

Attractants may also be used to reduce the fly population. A chemical bait has been developed that, when combined with an insecticide, forms a screwworm adult suppression system (SWASS) that reduces the fly population and the incidence of strikes. An examination of the efficacy of various methods of baiting showed that polythene sacs containing swarm-lure 2, a pungent mixture of 11 chemicals, attracted flies (not *C. bezziana*) for at least 2 weeks and was as efficient as jar bait. This result needs confirming in a screwworm-endemic country.

WOHLFAHRTIOSIS (FLESH FLY, WOHLFHARTIA MAGNIFICA)
Cutaneous infestation by larvae of the sarcophagid fly, *Wohlfartia magnifica*, has become a major disease of domestic livestock, including birds managed extensively (e.g., geese) in the Mediterranean basin, eastern Europe, and western regions of China. The disease is particularly significant for sheep in these regions, where it is more prevalent than strike by the calliphorid fly, *L. sericata*.

Other species of this genus are known from North America, but they do not infest domestic species. They are predominantly reported in very young rodents and birds, although there are occasional reports in infants. Mortality of infested hosts tends to be very high.

LIFE CYCLE AND EPIDEMIOLOGY
Larvae of this species are obligatory parasites developing only in the living flesh of warm-blooded vertebrates. They are not host specific.Adults are typical for this group of flies, being dark gray in color with three distinct black stripes on the thorax where the wings are attached. Female flesh flies, which are active during the warm parts of the day, deposit first instars on the host, usually in small groups of 15 to 20. Each female may produce up to 170 larvae. Completion of the three larval stages takes from 5 to 7 days, after which the mature third instars leave the lesion and fall to the ground, where they pulate. Development of the fly within the pupa is regulated by temperature and may require between 7 and 21 days.

Larvae are usually deposited near small wounds (bites of blood-feeding arthropods are sufficient to attract the larvae), but the favored sites appear to be the genitalia. Irritation of the vulva associated with the use of vaginal sponges for estrus synchronization may be a predisposing factor in sheep. Flies are active between April and October, with several generations being produced. Little information is available on overwintering. Wildlife are suspected as being reservoir hosts, but little information is available on which are the most important.

PATHOGENESIS
Larvae have well-developed mouthhooks that are used to abrade the skin surface, and with the aid of a wide variety of salivary enzymes, they quickly produce a dramatic lesion. Lesions increase in size as the larvae grow and require additional fresh tissue. Each animal may have one or more focal lesions, each packed with larvae. In severe cases several lesions may coalesce into one larger site.

Animals are often struck multiple times during a season, suggesting the absence of protective immunity. This adds to the impact of this disease because animals must be constantly monitored.

CLINICAL PATHOLOGY AND NECROPSY FINDINGS
A clinical examination is all that is necessary to make the diagnosis. Larvae can be distinguished from those of the screwworm or strike flies by the presence of a large posterior cavity surrounded by a number
of prominent tubercles. However, specific identification should be done by a specialist. Larvae should be preserved in 70% ethanol.

Affected animals are clearly stressed, showing restlessness and anorexia. Lesions formed at the vulva or prepuce are the most significant, causing great discomfort and dysfunction. Lightly infested animals shown no impairment of productivity. Infested animals develop strong antibody responses to salivary secretions, particularly of the third instars.

**TREATMENT**

There are currently no products specifically registered for management of this disease. Evaluations of several drugs and treatment approaches have been made. Of particular interest is the equivocal results of trials with macrocyclic lactones. In sheep, ivermectin and moxidectin had no effect on existing infestations and no prophylactic effect or only short protection against early instars. In contrast, doramectin provided complete prophylactic protection for 21 days and significant reductions for 40 days.

The insect growth regulator dicyclanil has also been evaluated and shown to reduce prevalence of infestation in sheep. The reduction not only occurred in treated animals, but was seen in untreated herdmates, possibly as a result of the overall reduction in fly numbers.

**RECOMMENDATION**

Animals likely to be attractive to these flies should be checked weekly, and appropriate treatment should be applied as soon as fly larvae are detected.

### Mite Infestations

#### HARVEST MITES (CHIGGER MITES)

Infestations with trombidiform mites cause dermatitis in all species. Except for *Psorergates ovis, P. bos, and Demodex spp.*, they are referred to as harvest or grain mites. These mites are primarily predatory on other arthropods associated with harvested grain and infesting animals only secondarily and usually transiently. It is usually the larval stages that are found feeding on animals, whereas the nymphs and adults are free-living. Hair loss and patchiness in cattle that are extremely well bedded often results from these mites but can be confused with louse infestations.

The larvae of *Pyemotes ventricosus, Neotrombicula autumnalis, Neotrombicula heptineri, Eutrombicula alfredaidgesi, Eutrombicula splendens, Eutrombicula batatus, Trombicula spp.*, and some species of *Lep-totrombidium and Schoengastia* are parasitic on humans and most animals, causing dermatitis and, in humans, transmitting rickettsial diseases. Nymphs and adults are free-living predators feeding mainly on arthropods in grain and hay. The larvae are most active in the autumn at harvest time and may cause dermatitis in animals grazing at pasture or those confined in barns and being fed newly harvested grain.

Horses, cattle, and goats are usually affected on the face and lips, which, in white-faced horses, may suggest a diagnosis of photosensitization, and around the feet and lower limbs, especially in the flexures. Affected areas are itchy and scaly, but with rubbing, small fragile scabs and absence of hair may become apparent. Infestation of horses with *Trombicula sarcina* causes a severe pruritus, and yearlings show irritation by lip-biting their legs and rubbing against stable walls. Stamping is uncommon and usually occurs when yearlings are stabled on fresh, contaminated bedding. Sheep, when first affected, stamp their feet repeatedly and bite their legs. The skin at the heels, coronet, and pasterns, and sometimes the shank, becomes erythematous and weeps fluid. The mites detach after 3 to 5 days and leave a small ulcerated area. In light infestations the mites may be confined to the area between the accessory digits, but in heavy infestations the skin over the whole of the lower limbs may be swollen and thickened. The infestation is self-limiting, and treatment is not usually necessary.

Infestation with *Tyroglyphus* spp. in pigs appears to be manifested by itchiness and the development of fragile scabs about 3 cm in diameter scattered over the body. Unlike the thick scabs of sarcoptic mange, the skin beneath appears normal. The infestations occur in pigs eating dry ground grain from automatic feeders, with lesions appearing several weeks after the dry feeding is begun and disappearing spontaneously about 3 weeks later. No treatment is necessary. Affected pigs show no ill-effects, but the lesions may be mistaken for those of swinepox or sarcoptic mange. The ingestion of large numbers of mites appears to have no ill-effects.

Recent work on the role of *N. autumnalis* has suggested that these mites are capable of acting as reservoirs of *Borrelia burgdorferi*, but this remains to be established.

**RECOMMENDATIONS**

No treatment is usually recommended, but a macrocyclic lactone will be effective if a treatment is required.

**REFERENCES**

parts of the flank and the hindquarters, and the wool tufts have a chewed appearance.

CLINICAL FINDINGS
Diagnosis depends on finding the mites in a skin scraping. The selection of sheep with excess scurf and fleece derangement increases the chance of finding mites, and in the absence of lice, ked, and grass seed infestation, about 75% of such sheep prove positive for *P. ovis*. The wool should be clipped as close as possible, the skin smeared lightly with oil, and then scraped over an area of about 25 cm². The mites have a seasonal incidence and may be very difficult to find in summer and autumn. For best results the scraping should be made on the ribs or shoulder in winter or spring. Scrapings are usually teased out in oil and examined microscopically without digestion. A number of scrapings may be needed from each sheep before mites can be demonstrated. Because of the difficulty of finding mites in summer and autumn, sheep dipped at that time cannot be said to be free of infestation until they prove negative on skin scraping in the following spring, when mite numbers should be at the highest levels.

TREATMENT AND CONTROL
There is no compound available that will eradicate itchmite after a single treatment. Arsenic, lime sulfur, and finely divided sulfur have been used and markedly reduce the number of mites. Because the mites are slow to build up, dipping every second year will mask the signs of infestation. However, arsenic is no longer used in most countries. Finely divided rotenone by itself or mixed with the synergist piperonyl butoxide reduces the mite population. It is usually combined with an organophosphate to include lice and ked control in the one product. Phoxim, an organophosphorous compound, has good activity, but two dippings 1 month apart are necessary to eradicate infestations. Amitraz causes a marked reduction in mites that will be maintained for some months.

A single subcutaneous injection of 0.2 mg/kg ivermectin freed sheep of mites for up to 56 days posttreatment. However, these sheep would have to be examined over a longer period to ensure eradication. Other macrocyclic lactone products, in various formulations, have been shown to have good efficacy. The absence of reports of itchmites over the last 15 years would suggest that the widespread use of macrocyclic lactone products has decreased the prevalence of infection.

DEMODECTIC MANGE (FOLLICULAR MANGE)
Mites of *Demodex* spp. infest hair follicles of all species of domestic animals. The disease causes little concern, but in cattle and goats there may be significant damage to the hide, and, rarely, death may result from a secondary bacterial invasion.

ETIOLOGY
Mites infesting the different host species are considered to be specific and are designated as *Demodex bovis* for cattle, *Demodex ovis* for sheep, *Demodex caprae* for goats, *Demodex equi* for horses, and *Demodex phylloides* for pigs.

Demodicosis may occur in farm animals of any age, especially those in poor condition, but most cases in cattle occur in adult dairy cattle in late winter and early spring. This differs from the well-known condition in the dog, which occurs in young, immuno-deficient animals.

LIFE CYCLE AND EPIDEMIOLOGY
The entire life cycle is spent on the host. Adult mites invade the hair follicles and sebaceous glands, which become distended with mites and inflammatory material. The life cycle passes through the egg, larval, and two nymphal stages. The disease spreads slowly, and transfer of mites is thought to take place by contact, probably in early life. Calves can acquire mites from an infected dam in half a day. However, in horses, grooming instruments and rugs may transmit infection.

PATHOGENESIS
Invasion of hair follicles and sebaceous glands leads to chronic inflammation, loss of the hair fiber, and, in many instances, the development of secondary staphylococcal pustules or small abscesses. It is these foci of infection that cause the small pinholes in the hide that interfere with its industrial processing and limit its use. In most farm animals, the lesions are difficult to see externally, and only the advanced ones will be diagnosed.

CLINICAL FINDINGS
The important sign is the appearance of small (3-mm-diameter) nodules and pustules, which may develop into larger abscesses, especially in pigs and goats. The small lesions can be seen quite readily in short-coated animals and on palpation feel like particles of bird-shot in the hide. In severe cases there may be a general hair loss and thickening of the skin in the area, but usually there is no pruritus, and hair loss is insufficient to attract attention. The contents of the pustules are usually white in color and cheesy in consistency. In large abscesses the pus is more fluid. In cattle and goats the lesions occur most commonly on the brisket, lower neck, forearm, and shoulder, but also occur on the dorsal half of the body, particularly behind the withers. Larger lesions are easily visible, but very small lesions may only be detected by rolling a fold of skin through the fingers. In horses the face and around the eyes are predilection areas. Demodicosis in pigs usually commences on the face and spreads down the ventral surface of the neck and chest to the belly. There is little irritation, and the disease is observed mainly when the skin is scraped at slaughter. The disease may be especially severe in goats, spreading extensively before it is suspected and in some instances causing death. Severe cases in goats commonly involve several skin diseases, such as mycotic dermatitis, ringworm, besnoitiosis, and myiasis. Demodicosis is rare in sheep. In this species pustules and scabs appear on the coronets, nose, and tips of the ears, and around the eyes, but clinical signs are not usually seen, and mites may be found in scrapings from areas of the body not showing lesions.

CLINICAL PATHOLOGY
The characteristically elongated mites are usually easy to find in large numbers in the waxy material that can be expressed from the pustular lesions. They are much more difficult to isolate from squamous lesions. Lesions in hides can be detected as dark spots when a fresh hide is viewed against a strong light source. However, lesions may not be readily seen until the hair has been removed and the skin has been soaking for some time.

DIFFERENTIAL DIAGNOSIS
- The commonest error is to diagnose the disease as a nonspecific staphylococcal infection.
- In cattle and goats the disease often passes unnoticed unless the nodules are palpated.
- Deep-seated ringworm in horses has much in common with demodicosis.
- A satisfactory diagnosis can only be made by demonstration of the mite.

TREATMENT AND CONTROL
Repeated dipping or spraying with the acaricides recommended for other manges is usually carried out but is more to prevent spread than to cure existing lesions. Ivermectin, which does not eradicate the infection in dogs, possibly because of the difficulty in getting the acaricide to the mite, has been reported to cure 98% of beef bulls when used at 0.3 mg/kg. Recent developments in the development of diagnostics may allow newer techniques that will effectively detect infestations.

REFERENCE

SARCOPTIC MANGE (BARN ITCH)
Sarcoptic mange occurs in a wide variety of host species and causes a severe pruritic dermatitis. Although in most countries it has been a major problem and was a reportable
disease, the advent of macrocyclic lactone endectocides has reduced the incidence of disease dramatically.

ETIOLOGY
The causative mite, Sarcoptes scabiei, is usually considered to have a number of varieties, each generally specific to a particular host species. Morphologic, immunologic, and molecular research confirms the close relationship among the varieties, but it does not explain the biological differences, particularly with respect to host specificity. Because host specificity is not strict and transference from one host species to another can occur, there is some concern when attempting to control the disease.

Animals in poor condition appear to be most susceptible, but conditions, especially overcrowding, in which sarcoptic mange occurs often go hand in hand with poor feeding and general poor husbandry. The disease is most active in cold, wet weather and spreads slowly during the summer months.

LIFE CYCLE AND EPIDEMIOLOGY
Female mites form shallow burrows in the lower stratum corneum of the skin, in which they deposit eggs. Development for both sexes includes a larval stage and two nymphal stages before molting to the adult. All life-cycle stages, except the eggs, can be found moving on the skin surface and are thus easily transferred to other hosts. The normal exfoliation of the skin eventually exposes the tunnels, exposing eggs as well. The life cycle, from egg to adult, takes 10 to 13 days.

Although direct contact between hosts is the most effective method of transmission, inert materials such as bedding, blankets, grooming tools, and clothing may act as carriers. Adult mites do not usually survive for more than a few days away from the host, but in optimum laboratory conditions they may remain alive for up to 3 weeks. In pigs, adult mites are often the source of infestation for young pigs even though they show no signs of the disease. Large numbers of mites can often be found in the ears of normal sows, and the mites are transmitted soon after farrowing. Significant scratching does not occur until a hypersensitivity develops some 8 to 10 weeks later and may continue until slaughter. A small proportion of young pigs do not develop a hypersensitivity, and these become chronically infected.

Among domestic species, pigs are most commonly affected, but it is an important disease in cattle and camels and occurs in sheep. It has been a notifiable disease in most countries, because of its severity, but a decline in prevalence accompanying the advent of new therapeutics has resulted in the removal of this requirement in some countries. People handling infested animals may become infected, but lesions will disappear if further contact is prevented.

Infested animals develop protective immunity and are able to clear challenge infestations rapidly. A proportion of infested hosts do, however, remain chronically infected, and mite populations may show a postpartum recrudescence, thereby facilitating transfer to the susceptible offspring.

PATHOGENESIS
Young animals, in particular piglets, become infected in the first few weeks of life and develop a hypersensitivity within 8 to 10 weeks. This allergic phase lasts for 8 to 9 months, and during this time affected animals are constantly itchy. The disease, if untreated, progresses to a localized crust formation characteristic of a chronic hyperkeratotic state.

Many infestations in pigs have little or no effect on weight gain, although there is some controversy, and treatments improve productivity (see following discussion). There are suggestions in other hosts of reduced feed efficiency. In some pigs, the loss of condition, production, and vitality may be severe, and the appearance of affected animals is esthetically displeasing. Erythema, papules, and intense pruritus may be seen. Few mites may be necessary to cause a reaction in a previously sensitized animal. A chronic condition is uncommon but is seen in pigs with an immunodeficiency.

In cattle and camels, severe hypersensitivity lesions occur and often lead to death. Sheep initially show an intense pruritus and rub the affected part against fences or bite at the skin. Later papules and vesicles occur and the skin becomes thickened, covered with pale scabs, and the hair is lost.

CLINICAL FINDINGS
Early lesions are characterized by the presence of small red papules and general erythema of the skin. The affected area is intensely itchy and frequently excoriated by scratching and biting. Loss of hair, thick brown scabs overlying a raw surface, and thickening and wrinkling of surrounding skin soon follow. In pigs the lesions commence on the trunk; in sheep and goats on the face; in cattle on the inner surface of the thighs, the underside of the neck and brisket, and around the root of the tail; and in horses and camels on the head and neck. Except in sheep, where the lesions do not spread to the woolled skin, lesions become widespread if neglected, and such animals may show systemic effects, including emaciation, anorexia, and weakness. In neglected cases, death may occur.

The course of sarcoptic mange is rather more acute than in the other forms of mange and may involve the entire body surface of cattle in a period as short as 6 weeks.

CLINICAL PATHOLOGY
Necropsy examinations are not usually undertaken. Deep scrapings that draw blood are required for accurate diagnosis and must be taken from the edges of any evident lesions (scrapings taken from the central portions of lesions are very often negative). Examination of scrapings either directly or after digestion in 10% potassium hydroxide will reveal mites and/or eggs. When practical, multiple scrapings from affected animals should be taken. Examination of the ear wax of pigs often shows mites when none can be seen in scrapings.

Change in behavior, a result of the intense pruritus, has been used in swine as an initial diagnostic tool. An increase in the rubbing index is indicative of infestation, but other clinical confirmation is required.

An ELISA for detection of antibodies to Sarcoptes scabiei has been developed. The test has high specificity and moderate sensitivity, being more sensitive in young animals undergoing their first infestation. It has been shown to work well in herd-level eradication programs and functions afterward as an effective surveillance tool.

Recent description of the genome of a canine variety has elucidated several aspects of the host response and biology of the mite.1

Differential Diagnosis
- Sarcoptic mange is the only mange that occurs in pigs. It can be confused with infestation with Tyroglyphus spp. mites or lice, or with swinepox, parakeratosis, infectious dermatitis, pityriasis rosea, and ringworm. In most of these diseases there are clinical features that are characteristic, and final diagnosis can be made on the presence or absence of the mite.
- The same comments apply to the differentiation in cattle of sarcoptic mange from chorioptic and psoroptic mange and from chlorinated naphthalene poisoning and ringworm.
- Horses may be affected by psoroptic or chorioptic mange, but the lesions are most common at the base of the mane and tail and at the back of the pastern, respectively.
- Infestation with the trombiculiform mites and photosensitization may resemble sarcoptic mange.
- The disease is uncommon in sheep.

TREATMENT AND CONTROL
Macro cyclic lactone endectocides (including ivermectin, eprinomectin, moxidectin, and doramectin) are the preferred products for treatment of sarcoptic mange. Use of these products in pour-on or injectable formulations is highly efficacious when used at the label-recommended dose. Because of the residual activity of these compounds, retreatment is not usually necessary, although moxidectin given subcutaneously at 0.2 mg/kg to infested sheep resulted in a rapid clinical improvement but did not eliminate the mites. Two doses 10 days apart resulted in negative skin scrapings by 14 days.
posttreatment. A single injection to cattle eliminated the mites by day 14. The resolution of the lesions may take considerable time, but should not be misconstrued as product failure.

Prefarrowing treatment of sows with ivermectin to prevent transmission to the newborn piglets improves weight gain and early feed conversion.

Although buildings, bedding, and other inert materials do not support the mite for more than a few days, they should also be treated unless they can be left in a dry state for 3 weeks.

**RECOMMENDATION**

Always treat affected animals. To control spread, animals should be isolated or quarantined.

**REFERENCE**

---

**PSOROPTIC MANGE (SHEEP SCAB, BODY MANGE, EAR MANGE)**

Psoroptic mange is of greatest importance in sheep, in which it causes sheep scab, but it is also responsible for body mange in cattle and horses and ear mange in horses, sheep, goats, and rabbits. The disease is a major animal welfare concern.

**ETIOLOGY**

The various species of *Psoroptes* have now been reduced to two or three species. Based on molecular evidence, *Psoroptes ovis*, *Psoroptes cuniculi* and *Psoroptes cervinus* are identical despite differences in morphology and biology. It is clear that *P. ovis* from cattle and sheep are identical, although cross-transmission is not always successful. *P. equi* occurs on horses, donkeys, and mules in Great Britain and *P. natalensis* on cattle and the water buffalo. The ear mites are all *P. cuniculi*, and recent work has suggested this is a variant of *P. ovis* adapted to the aural environment. *P. cervinus* assumes a dual role, being an ear mite of the American bighorn and a body mite of the wapiti.

**LIFE CYCLE AND EPIDEMIOLOGY**

Psoroptic mange is a major disease in sheep that was once virtually eliminated in most progressive countries where wool production is an important industry. With the cessation of organophosphate dips in the United Kingdom there has been a resurgence of the problem. The disease in cattle was widespread in the United States but has now largely been brought under control. It can spread rapidly and cause serious losses in cattle if neglected, as shown by the serious losses that can occur in feedlots. The ear manges cause irritation and, in horses, a touchiness around the head.

Psoroptic mites abrade the surface and feed on lipid exudate, bacteria, and skin debris. Erythrocytes are not normally a constituent of the diet and may be accidentally ingested when host scratching results in skin breakage. They cause the formation of scabs, under which they live. The eggs are laid on the skin at the edge of a scab and hatch in 1 to 3 days, although this is prolonged if eggs are not in contact with the skin. There are the usual larval and nymphal stages, and the whole life cycle is complete in 10 to 11 days. All stages are capable of survival away from the host for up to 10 days, and under optimum conditions adult females may survive for 3 weeks.

Optimum conditions for development include high humidity and cool temperatures. Thus the disease is most active in autumn and winter months. This is a result of not only the increased activity of the mites but also the more rapid development in housed animals and the tendency for the disease to be most severe in animals in poor condition. When conditions are adverse, as in summer, mites survive in sheep in protected parts in the perineum, in the inguinal and interdigital regions, in the intraorbital fossae, and inside the ear and the scrotum. Spread occurs from sheep to sheep, but transmission from infected premises and by passive spread of pieces of wool also occurs.

The life cycle of the other species is thought to be similar. Spread of ear mite in horses can occur by grooming or by the use of infected harness.

**PATHOGENESIS**

The mite migrates to all parts of the skin and prefers areas covered with hair or wool. Salivary secretions and mite excreta contain proteinases that result in a severe allergic pruritus. The exudation of serum accumulates to form a crust. In cattle the mites are most active at the edge of the crust, and the lesion spreads peripherally. Infested calves have lower weight gains, lower feed conversion, and lower energy retention than non-infested calves. In sheep the mites are more generally distributed, and bacterial invasions of the skin are more common.

**CLINICAL FINDINGS**

**Sheep**

Cutaneous lesions may occur on any part of the body, but characteristically in badly affected sheep they are most obvious on the sides. Very early lesions are small (6-mm-diameter) papules that ooze serum. Attention may be attracted to the area by raggedness of the wool caused by biting and scratching. In older lesions thin yellow crusts are present, and the wool commences to shed. The wool may contain large masses of scab material that binds the fibers together in a mat. Under suitable conditions the infestation spreads rapidly, and in 6 to 8 weeks three-quarters of the body may be affected.

In a typical outbreak of sheep scab many animals are affected and show itchiness and shedding of the fleece. Some become markedly emaciated and weak, and deaths may occur. However, it is possible to have the disease in a flock at a very low level of incidence and with minimal lesions. This usually occurs when the sheep are highly resistant because of good nutrition, climatic conditions are adverse for mite development, or treatment has been carried out but has been incomplete. In such cases there may be little or no clinical evidence of the disease, and a careful search for latent cases may be necessary. This is facilitated by packing the animals into a confined space, so that the mites become active, and watching for signs of itchiness.

Behavioral changes in infested sheep are dramatic, with sheep biting at the affected areas and rubbing or scratching. In addition, infested sheep exhibit stereotypic behaviors typical of animals under stress. These changes combine to reduce productivity. Animals exhibiting these changes should be carefully examined by palpating the surface of the skin in search of papules and scabs. Special attention should be paid to the ears, the base of the horns, the infraorbital fossa, and the perineal and scrotal areas in rams.

**Goats**

Lesions can vary from a dry crusty scab on the external ear canal with no clinical signs to severe lesions covering much of the body and causing death. However, it is commonly an ear mite, feeding on whole blood and causing the production of scabs that vary from a single layer lining the large sulcus at the base of the concha to abundant laminated scab formation occluding the meatus. In severe cases the poll may be affected, and scabs may also be found on the pasterns. Female goats serve as the source of infection for the kid; mites may be found by 5 days, and clinical signs are seen by the 3rd week of life. *Raillietia* may also be found in the ear of goats, but *Raillietia caprae* is easily differentiated microscopically because all legs are on the anterior part of the body.

**Horses**

*P. equi* causes the production of large, thick crusts on those parts of the body carrying long hair, such as the base of the mane and the root of the tail, and hairless areas such as the udder, prepuce, and axilla. Affected parts are itchy, the hair is lost, and with constant rubbing the surrounding skin becomes thickened. *P. cuniculi* infestations in horses cause severe irritation in the ear accompanied by discharge, shaking of the head, rubbing of the head, and tenderness of the poll.
Cattle

Typical lesions appear first on the withers, neck, and around the root of the tail. In severe cases they may spread to the rest of the body. The lesions are intensely itchy. They commence as papules but soon are covered by a scale, which enlarges peripherally and coalesces with other lesions so that very large areas of skin may become involved. The hair is lost and the skin becomes thickened, wrinkled, and covered with scabs. Badly affected animals becomes weak and emaciated and may die.

CLINICAL PATHOLOGY

The mites can be easily demonstrated in scrapings taken from the edges of the lesions. Examination is facilitated by prior digestion of the scraping in warm 10% potassium hydroxide solution.

An ELISA has been developed for diagnosis of Psoroptes infestation in sheep. It has been applied to monitoring of infestations as part of efficient control programs.

DIFFERENTIAL DIAGNOSIS

- Severe cases of psoroptic mange in sheep are similar to myotic dermatitis except that there is no itching in the latter. Diseases causing itching, such as scrape, ked, and louse infestations and infestations with Psorergates ovis and harvest mites, do not have typical cutaneous lesions, and the latter group can usually be detected by examination for the causative parasites.
- In horses, attention is drawn to the condition because of the horse rubbing its head, by swelling around the base of the ear, or by resentment to the bridle passing over the ears. In some horses, the affected ear may droop.

TREATMENT AND CONTROL

Macrocyclic lactone endectocides are used most frequently for control of psoroptic scabies. Cattle treated with ivermectin must be separated from noninfested cattle for between 9 and 14 days; otherwise, spread and reinfection may occur. In sheep two treatments of ivermectin 0.2 mg/kg subcutaneously are necessary to eliminate infestations.

Moxidectin applied as a 0.5% pour-on at 0.5 mg/kg to cattle is effective against P. ovis lice, and Chorioptes bovis, and it was equally effective against P. ovis as 0.2 mg/kg by subcutaneous injection. In sheep, although a single subcutaneous dose of 0.2 mg/kg moxidectin gave a rapid clinical improvement, two doses 7 days apart were necessary to eliminate mites. In large-scale field use, sheep receiving a single injection in the autumn remained free of the infestation throughout the winter, and two injections 10 days apart were effective in treating outbreaks.

Doramectin injectable at 0.2 mg/kg SC was highly effective in eliminating mites in scrapings of infested cattle. The same treatment was found to protect cattle from infestation for up to 3 weeks.

If sheep are to be dipped, it is important to wet the skin thoroughly and pay special attention to severe cases where mites are likely to be present in inaccessible sites on the body. Thus a plunge dip is almost essential, and the sheep must be kept immersed in the dipping fluid for at least 1 minute. Prior shearing may be advisable but may lead to further spread of the infestation. Care must be taken to ensure that the concentration of the acaricide in the dip is maintained, especially when large numbers of sheep are being treated. Badly affected animals should be set aside, and inaccessible sites, including ears, horn bases, and perineum, should be treated manually with the dipping fluid. Dipped sheep should not be returned to their pastures or to the barn unless the latter has been thoroughly cleaned and sprayed with the dipping fluid.

The synthetic pyrethroids are variable in their efficacy. Flumethrin, used as a nonstripping dipping compound, eradicated P. ovis from sheep when used at 55 ppm and gave at least 7 weeks of protection.

In horses, affected ears should be cleaned of all wax, and ear preparations containing benzene hexachloride should be used at weekly intervals. Benzyl benzoate is a safe and effective treatment when given every 5 days for three treatments. Ivermectin is highly effective against P. equi.

Eradication of sheep scab on an area basis is usually undertaken by quarantine and compulsory treatment of all susceptible animals in the area at the same time. Now that there are effective treatments that do not require dipping, eradication of scab from areas should be more easily accomplished. The necessity to dip all animals in the area during a short period presents difficulties, and the cost of construction of dips and lack of desire to dip in cold climates are other obstructing factors. The use of pour-ons or injections is an attractive alternative to autumn dipping and has the added advantage of providing helminth control in late-season lambs and in ewes. Further, even pregnant animals can be yarded and treated by subcutaneous injection or pour-on as long as care is taken in the yards. Where it is desired to keep the disease at a low level short of eradication, the disease is made notifiable, movement of stock is restricted, and infested farms are quarantined.

RECOMMENDATION

Treatment is absolutely necessary to keep this from becoming an animal welfare issue.

REFERENCES

CHORIOPTIC MANGE (TAIL MANGE, LEG MANGE, SCROtal MANGE)

Chorioptic mange is the commonest form of mange in cattle and horses. Although the primary effect on cattle is esthetic damage, there are production effects in dairy animals. In horses, leg mange is a source of annoyance and inefficiency at work. In sheep, it affects the scrotum and may cause a decrease in fertility.

ETIOLOGY

Chorioptic mites were formerly named according to the host species, but those on cattle, horses, goats, and sheep are now considered to be one species, Chorioptes bovis. Another species, Chorioptes texanus, has been reported on goats, cattle, and Canadian reindeer. In cattle, the mites are much more active in the latter part of the winter and tend to disappear in cattle at pasture. This diminution in activity is not noted in cattle kept housed in the summer.

LIFE CYCLE AND EPIDEMIOLOGY

C. bovis feed on the skin surface, abrading the upper layers with their mouthparts and contaminating the area with salivary secretions and excreta. Developmental stages are similar to that of Psoroptic, and a complete cycle, from egg to adult, requires approximately 3 weeks. The number of parasites is influenced by temperature and humidity, with the mite populations beginning to increase on sheep in early autumn and numbers reaching a peak in late autumn or early winter and declining in spring. In cattle the cycle is longer, with peak numbers occurring in late winter and early spring and declining in summer. Transmission is probably effected by direct contact in most instances, although in animals housed in barns, grooming tools may be an additional method of spreading the disease. Infestation of bedding is not a common method of transmission.

In horses, the parasites occur almost entirely in the long hair on the lower parts of the legs and are rarely found on other parts of the body. In cattle the disease is most evident in the winter, with lesions occurring most commonly on the perineum and back of the udder, extending in severe cases to the backs of the legs and over the rump. In the summer months, the mites persist in the area above the hooves, particularly the pasterns of the hind leg. In sheep, lesions are confined to the wool-less areas, chiefly the lower parts of the hindlegs and scrotum. Rams are more heavily infected than ewes and probably infect ewes while copulating. Lactating ewes probably act as the source of infection for lambs.

PATHOGENESIS

The mites cause an allergic exudative dermatitis; the yellowish serous exudate coagulates
and breaks as the hair grows so that small scabby lesions are seen on the hair. In horses the mites cause severe irritation and itchiness. The initial lesion in cattle is a small nodule that exudes serum, causing matting of the hair. In severe cases these coalesce to form heavy scabs and cause thickening and wrinkling of the skin. Mites can be isolated from many animals that show no clinical evidence of the disease. Although most cases do not cause any symptoms, a rapidly spreading syndrome characterized by coronitis, intense irritation, and a marked fall in milk production has been reported.1 C. bovis is a common parasite of sheep in the United States, New Zealand, and Australia, and causes an allergic exudative dermatitis on the scrotum of rams. This may cause a rise in temperature of the scrotal contents and severe testicular degeneration if the lesion has an area greater than 10 cm².

**CLINICAL FINDINGS**
The first sign in horses is usually violent stamping of the feet and rubbing of the back of the hind pasterns on wire, rails, or stumps. This is most evident during periods of rest and at night. Examination of the area is difficult because of the long hair present, and the horses may resent manipulation. In cases of long duration, the skin is seen to be swollen, scabby, cracked, and usually greasy; small amounts of serous exudate may be attached to most hair in the affected area.

Cattle show little evidence of cutaneous irritation, but the small crusty scabs (3 mm in diameter) on the escutcheon, udder, and thighs are unsightly. Although the mites appear to cause little trouble in the summer, occasional animals are seen that have thick, crusty scabs on the skin, just above the coronets and around the muzzle.

The main lesion in sheep is seen on the scrotum of rams, where an allergic dermatitis results in the production of a yellowish serous exudate over areas from a few millimeters to several centimeters.

**CLINICAL PATHOLOGY**
Scrapings from the affected areas usually contain large numbers of mites.

**DIFFERENTIAL DIAGNOSIS**
Greasy heel in horses resembles choriomitic mange except that pain is more evident in the former and itchiness in the latter. It has been suggested that the two diseases are etiologically related.

The lesions in cattle may go unnoticed but are not likely to be mistaken for those of any other disease, with the possible exception of other manges. The presence of choriomitic mites in footrot and mucosal disease lesions may be purely coincidental, but cases of choriomitic mange that have lesions around the coronet and muzzle may be mistaken for one of the erosive diseases.

Sheep with itchy, scabby legs may be infested with other forms of mange or have contagious ecthyma or strawberry footrot.

**TREATMENT AND CONTROL**
The macrocyclic lactone endectocides have shown efficacy against Choriomites spp., but eradication of the parasites from a herd is difficult. Moxidectin 0.5 mg/kg applied as a pour-on eliminated C. bovis as well as sucking lice and P. ovis. When given as a single injection of 0.2 mg/kg, there was a marked decline in the number of mites, but few cattle were cleared of infection. Duramectin has high efficacy at the label rate in cattle, but a single treatment did not clear mites from all of the trial animals. Treatment with eprinomectin at recommended rates was completely effective, but mites persisted for at least 14 days.

Amitraz 0.05% removed 98% and phoxim 0.05% and 0.1% used twice at 10-day intervals has also eradicated the infection from cattle. Other compounds if used repeatedly will reduce mite numbers, but recrudescence may occur. Ivermectin 0.2 mg/kg given subcutaneously on two occasions reduced but did not eliminate the infestation on cattle. A single treatment of infested horses with ivermectin paste also did not remove all mites, but when combined with hair removal, washing encrusted areas with oil of salicylic acid, and the later removal of crusts with a stiff brush, eradication was achieved.

**REFERENCES**

**Ked and Louse Infestations**
Ked and louse infestations cause irritation resulting in skin or wool damage. Blood loss may occur with some species.

**SHEEP KED (MELOPHAGUS OVINUS)**
Keds are flat, brown, wingless flies, about 6 to 7 mm in length, found on sheep throughout the world. Keds are now rarely reported in many countries because of good management and control. For example, it wasn’t mentioned in a review of livestock ectoparasites of Europe and the Mediterranean, although anecdotal evidence suggests it may be present in isolated pockets associated with organic production. The ked can transmit Trypanosoma melophagium and Rickettsia melophagi, harmless blood parasites of sheep. Recent studies suggest that it may have more importance than otherwise indicated. Staining of the wool by the feces of the ked reduces its value and gives it a peculiar musty odor. Heavy infestations cause skin blemishes, which are costly to the leather industry. Sheep in poor condition suffer most from infestations. Goats may also be infested.

**LIFE CYCLE**
Keds live their entire life cycle on the host. Adults of both sexes are blood feeders, and although the degrees of infestation usually encountered cause only irritation with resulting scratching, biting, and damage to the fleece, very heavy infestations may cause severe anemia. Spread is generally the result of direct contact between hosts. A recent review suggests that this exchange is primarily between dams and their offspring and that it is predominantly the newly emerged adults that migrate to new hosts. Larvae develop within the female one at a time and are deposited on the host as mature third instars that puate within a few hours. The female ked lives for 4 to 5 months and may lay up to 10 to 15 larvae, so buildup of infestations is slow. The larvae are attached to the wool fiber some distance above, the skin and many larvae and pupae are removed at shearing. The young ked usually emerges in 20 to 22 days, but this period may be prolonged for up to 35 days in winter. The complete life cycle takes 5 to 6 weeks under optimal conditions. Heavy infestations usually occur in winter months, and they decline in the summer. The parasite is mainly seen in colder, wetter areas, and infestations may disappear when sheep are moved to hot, dry districts. Resistance is acquired in time, and resistant sheep grow better and produce more wool.

A seasonal pattern of infestation occurs. Keds are sensitive to hot, dry weather and numbers decrease markedly over the summer. Populations increase slowly over the autumn and winter. Although keds that have been dislodged from the host can live for up to 2 weeks if in mild moist conditions, most die in 3 to 4 days and probably do not play a part in reinfecting sheep.

Keds have recently been implicated in the transmission of Anaplasma ovis from infected sheep. This potentially zoonotic disease can infect people, with important implications.

**CONTROL**
At shearing a large proportion of adults and pupae will be removed. This can provide effective control on adult sheep, particularly where a combination of hot conditions and a short fleece will kill most of the remaining keds. However, some may remain alive in protected places such as the ventral neck and breech regions and on younger stock. If treatment is carried out within the next 2 to 4 weeks, eradication will be achieved as long as all sheep are included and the insecticide
used has a residual protection longer than the time taken for the last pupae to hatch. Ivermectin and its analogs given at the standard anthelminthic dose will act to eliminate the ked populations. Clofamben is also effective against keds.

LOUSE INFESTATIONS (PEDICULOSIS)

Louse infestations are common throughout the world. The species are host specific and are divided into biting and sucking lice.

SYNOPSIS

Etiology Species-specific sucking and chewing lice affecting all animals.
Epidemiology Transmission from host to host. Lice show a marked seasonal periodicity, rising from low numbers after summer to a peak in the following late spring. Foot lice infested from pasture.
Clinical signs Irritation that causes rubbing, damage to the fleece or skin, and loss of milk production. Some species cause anemia. Foot lice cause stamping.
Clinical pathology Hair loss may result from hypersensitivity.
Lesions Skin lesions as a result of rubbing; fleeces have tufts protruding and lose their brightness.
Diagnostic confirmation Lice can be seen on careful inspection. Preferred site varies with host and species of louse.
Differential diagnosis in sheep, must be differentiated from Psoroptes, ked, and Psoroptes infections. In other animals, separate from allergic dermatitis.
Treatment Macrocytic lactones and synthetic pyrethroids (where available).
Control Pour-on and injectable treatments control lice on cattle, horses, sheep, and pigs. Good husbandry practices will reduce infestations. Plunge or shower dips used on cattle, horses, sheep; all sheep should be treated, and sheep must be thoroughly wetted. Treatment should follow shearing, which removes many lice; sheep in short wool are also easier to wet.

ETIOLOGY

The important species are as follows:
- Cattle:
  - Sucking lice—Linognathus vituli (long-nosed sucking louse), Solenopotes capillatus (small blue sucking louse), Haematopinus eurysternus (short-nosed sucking louse), Haematopinus quadrirruptus (tail louse), Haematopinus tuberculatus (buffalo louse)
  - Sheep:
    - Sucking lice—Linognathus ovillus (sucking face louse), Linognathus africanaus, Linognathus stenopsis (goat sucking louse), Linognathus pedalis (sucking foot louse)
    - Goats:
      - Sucking lice—L. (blue louse), L. africanaus
      - Chewing lice—Damalinia caprae, Damalinia limbata, Damalinia crassiceps
    - Pigs:
      - Sucking lice—Haematopinus suis
    - Horses:
      - Sucking lice—Haematopinus asini
    - Donkeys:
      - Chewing lice—Werneckiella (= Bovicola) ocellatus

LIFE CYCLE AND EPIDEMIOLOGY

Sucking Lice

All life-cycle stages of sucking lice are found on the host. Both sexes are obligate blood feeders, taking small meals from capillaries in the upper skin. Survival off the host is limited, although some species, such as the foot lice of sheep, may survive away from the host for up to 2 weeks. Females lay 2 to 6 eggs per day, which are attached to individual hair shafts. Eggs complete embryo development and hatch within 5 to 11 days of deposition. Lice have three nymphal stages, which bear a morphologic similarity to the sexually mature adult stage. Each nymphal stage will take 2 to 4 days to complete. Louse development rate, at all stages, is highly temperature dependent and requires a narrow temperature range. Temperatures above 41° C (115° F) to be lethal for eggs and adults, respectively, of L. vituli. Optimal development takes place between 33°C and 37°C (91 F and 99 F). Lice therefore show a seasonal periodicity, with very low numbers in the summer when conditions are hot. Populations begin to increase with cooler fall temperatures, reaching maximum levels in late winter.

Chewing Lice

All life-cycle stages of chewing lice are found on the host. Lice feed on dead skin cells, hair, and oil secretions, which they abrade from the surface using their chewing mouthparts. There may be some abrasion of the upper skin layers, and there has been demonstration that sheep develop antibodies to salivary sections of Damalinia (= Bovicola) bovis. Sex ratios are highly female biased, and there are suggestions that parthenogenesis occurs in some species. Females deposit less than 1 egg per day. Embryo development is completed in 7 to 10 days, producing nymphs that molt three times before reaching sexual maturity. As with the sucking lice, there is a strong temperature/development relationship that is highly regulated, with a narrow range for optimal development and survival. Chewing lice can survive off the host for up to 2 weeks.

Transmission of both types of lice occurs by direct contact, but inert objects such as blankets, grooming tools, and harnesses may remain infective for several days. Sheep may become infested with foot lice from the pasture. Young pigs may become infected some 10 hours after birth. Newborn calves rapidly acquire infestations from their dams.

CLINICAL FINDINGS AND DIAGNOSIS

Sucking Lice

All species cause irritation of the skin and stimulate scratching, rubbing, and licking, leading to restlessness, damage to hair coat or fleece and hides, and loss of milk production. These behavioral changes result in reduced efficiency, particularly in feedlot cattle.

Lice appear to be present on a large proportion of cattle, but measurement of their impact on productivity has produced equivocal results. It is often thought that infestation has little or no effect on weight gain and hematological values. However, there appears to be a synergistic effect between louse infestations and the presence of gastrointestinal nematodes that does have an influence on weight gain. Anemia is rare but has been described for heavy infestations of L. vituli and H. eurysternus. Treatment, however, may be warranted to reduce the damage to hides and prevent damage to fences and other fixtures. Hairballs may occasionally occur in calves as a result of continual licking. Cattle and pig lice have been reported as vectors of several rickettsial diseases, but this remains to be verified.

The pig louse spreads swinepox, and although weight loss may not occur, even with heavy burdens, some pigs develop an allergic dermatitis, and the consequent rubbing leads to skin lesions.

Foot lice of sheep are thought to live on blood. Light infestations may not cause clinical signs, but moderate to severe infestations cause stinging and biting of the affected parts. Lice cause goats to rub or to bite their coats, which become matted and damaged. Angora goats can damage the hair shaft and lose their coats. Signs of infestation are restlessness, hair loss, and decreased milk production. In horses, H. asini is the more serious species because it removes blood and may cause some anemia.

Chewing Lice

Chewing lice cause irritation and rubbing. In sheep, the wool loses its brightness and may become matted and more yellow. There is evidence that a pelt defect called cockle is
associated with infestation with body lice. The quantity and quality of the fleece is reduced, and losses up to AUS$3.20 per infested sheep have been measured.

Chewing lice on cattle also cause an increase in rubbing and licking, which contributes to reduction of efficiency and damage to facilities. Hair loss has been attributed to this infestation, but it is a controversial association because many other causes are likely. Lice have been implicated in the transmission of several bacterial pathogens, but this finding requires verification.5

Diagnosis of lice on cattle and horses requires close visual inspection, with particular attention being paid to known predilection sites. These include the head, the sides of the neck, the dewlap, the escutcheon, and tail switch. Effective diagnosis requires that hair be parted and skin examined at several locations at each of the predilection sites. Use of a supplementary light source and restraint of the animal are very helpful.

Chewing lice of cattle, sheep, and horses are recognized by their rounded heads and light brown color. These lice are highly mobile and will move away from inspection sites. Their eggs are difficult to see unless on dark-haired cattle or horses. Sucking lice are recognized by their gray or blue-gray color and their pointed heads. They tend to remain fixed to the skin.

Chewing lice may congregate on the dorsal surface and flanks, whereas sucking lice are found on the head and in the long hair of the mane and tail; in heavy winter infestations, however, lice may be found on any part of the body. In sheep with long wool, the greatest numbers of D. ovis may be seen on the midside, particularly the shoulders, from where they spread to the back and rump. After shearing, small residual infestations may be found on the ventral neck. Foot lice are usually found in clusters on those parts covered with hair, mainly on the lower limbs, but in heavy infestations they can be found in clusters above the hock, on the scrotum, in the belly wool, and, more rarely, on the face.

TREATMENT AND CONTROL
Self-grooming and grooming by herdmates effectively regulates louse populations on most hosts, but the effectiveness is limited when hair coat or fleece become too long for the tongue surface to effectively remove lice and eggs. Similarly, shearing is an important factor in reducing body lice populations on sheep. Between 30% and 50% of the population is removed with the fleece, and those remaining are subjected to a more variable microclimate. Populations are at their lowest 30 to 60 days after shearing. Reversing temperature gradients as sheep move in and out of shade, and very wet conditions, will also reduce lice numbers.

Body lice of sheep are relatively easy to eradicate if a clean muster is achieved, the sheep are thoroughly treated, and reinfestation is avoided. However, in practice, failure to eradicate commonly occurs as a result of the inability to thoroughly wet the fleece because of poor formulation of products or because the lice are resistant to the chemical used. The most difficult problem when attempting to eradicate lice from flocks over a large area is the diagnosis of lice in lightly infested flocks. Methods of detection of louse antibodies in fleece have been developed for use on the farm that give good results. Adoption has been limited, and in many cases the methods have been withdrawn from practice because the delay between testing and results has been too long. Similarly, techniques have been devised to test for lice by digesting the wool and examining the residue for lice, but the delays inherent in such a system often mean that by the time the farmer obtains the results, the optimum time to treat sheep has passed.

Affected sheep can be effectively treated with macrocyclic lactone or chinin synthesis inhibitors. An avermectin 0.03% jetting fluid was reported to have high efficacy in treating lice in sheep with 3 to 9 months of wool, but failed to eradicate the lice. No treatment is known that can eradicate lice from long-wooled sheep under field conditions. Following treatment of foot lice, sheep should be moved to a paddock that has been free of sheep for a month.

Treatment of goats has not been studied extensively, and the treatments used on sheep and cattle are thought to be effective in goats. Lactating goats should not be treated. Macroyclic lactone-based products (ivermectin, moxidectin, doramectin, and eprinomectin) are available as pour-on or injectable formulations for cattle and have shown excellent efficacy against both sucking and chewing lice. Persistence of activity is one of the exceptional benefits of these products.

Essential oil treatments using a variety of products have been evaluated against W. ocellatus in donkeys and have been proven an effective alternative to synthetic chemicals.8 Sheep lice have been shown to quickly develop insecticide resistance, and strains of D. ovis that are resistant to the insecticides are common in the United Kingdom and Australia.9 Tolerance has been reported in other species as well.10 Resistance management strategies that use combination treatments are now considered the best approach to management of the problem.

Treatments should be timed to coincide with the beginning of louse population growth (i.e., autumn or early winter). Extremely early treatments often result in spring outbreaks that are caused by very small residual populations on a few animals.3 Products with persistent activity, in excess of 21 days (e.g., macrocyclic lactones), do not require a second application.

Effective management of lice in a herd requires that new animals be isolated for a period of time sufficient for all lice to be eliminated by treatment. The introduction of one or two infested individuals, such as occurs when strays are allowed into a herd, leads to a slow buildup of infestation. In Australia, modeling approaches have been developed for the treatment of sheep.9

RECOMMENDATION
All animals in a herd should be treated for louse control to prevent the buildup of the louse population to a point that is damaging.

REFERENCES

Although these insects differ quite markedly, they are dealt with together because they exert similar deleterious effects. Their activity causes stress and induces behavioral changes, and in many cases they are important vectors for a variety of parasites and infectious diseases.

STABLE FLIES (STOMOXYS CALCITRANS)

ETIOLOGY
The stable fly, Stomoxys calcitrans, has a cosmopolitan distribution. Other species, including Stomoxys nigra, occur in South Africa. S. calcitrans is a moderate-sized, gray to black fly about the size of a housefly. These are the most economically important species of fly affecting confined livestock in North America.

LIFE CYCLE AND EPIDEMIOLOGY
These insects have a typical fly life cycle, with eggs being deposited in high-organic-matter areas with an elevated moisture content, such as spilled feed and the edge of silage pits. The larvae grow in a temperature-dependent manner in the same high-organic-matter area through three larval stages. Pupae form in dry material at the edges of the areas where the larvae develop. Flies rest on fences and structural surfaces in a characteristic head-upward position and can readily be recognized by the prominent, forward-directed, pointed proboscis between short palps.

Miscellaneous Skin Diseases Caused by Flies, Midge, and Mosquitoes
Stable flies of both sexes are blood feeders, attacking particularly cattle and horses, people, and, to a lesser extent, pigs. Bites are painful and often bleed freely when fresh. The flies are intermittent feeders, spending only short periods on the host; most of their time is spent resting on fences and building sides. Eggs are laid in high-moisture areas of rotting hay or straw, along the edge of silage pits, and on the edges of manure pack of feedlots and compost piles. Mature larvae leave the high-moisture sites to pupate in drier sites nearby. Development times are regulated by temperature, with higher temperatures resulting in more rapid development. A complete life cycle will require 3 to 4 weeks in summer. In temperate climates flies exhibit a distinct seasonality, with peak populations in middle to late summer. Larvae will overwinter in warmer areas of silage piles. The flies are highly mobile, traveling up to 20 km in search of suitable hosts. These flies have now moved onto pasture, where they can affect cattle that are fed from round bales left as a food source. Feeding activity by the flies results in stress to the animals and reduced efficiency through reductions in feeding time. When large numbers of flies are present, the animals will bunch to reduce biting rates. At high temperatures the bunching may result in cattle overheating.

**PATHOGENESIS**

*S. calcitrans* organisms are mechanical vectors for anthrax, infectious equine anemia, bovine virus, diarrhoea virus, and surra. They are intermediate hosts for the nematode *Habronema majus*, which is reputed to be a cause of allergic dermatitis in horses in Japan.

**CLINICAL FINDINGS**

A localized sensitivity of the forelimbs of cattle may develop and result in the formation of intradermal blisters that coalesce to form bleeding sores. With very heavy infestations some deaths may occur. Populations can be assessed by counting the number of flies on the front legs of cattle. When the average number exceeds 2 per leg, significant losses occur, and population management is required.

**TREATMENT AND CONTROL**

Effective management of stable flies requires removal of high-moisture, rotting organic matter from the environment. Edges of silage pits, manure packs, and compost piles should be kept dry, and manure-contaminated bedding should be removed regularly. Insecticide treatments must be applied to all exterior surfaces (e.g., barn sides, fences, and exterior of feed bunks). Spraying of fixtures and walls, particularly sunlit walls where the flies often remain unnoticed, with long-acting compounds reduces infestations for 2 weeks or longer.

Application of insecticides or repellants directly on animals is generally impractical because of the short duration of efficacy. Low frequency of insecticidal application, when necessary, slows the development of insecticide resistance. Permethrin applied as a microencapsulated formulation gave longer protection than an emulsifiable concentrate. Affected horses can be treated locally with an analgesic cream, and if the irritation is severe they can be tranquilized with acepromazine.

**RECOMMENDATION**

Treatment is absolutely necessary to keep these flies from reaching population levels that are in excess of the economic threshold and from reaching levels where they are an animal welfare issue. Populations are also an issue for humans.

**HORSE FLIES, MARCH FLIES OR BREEZE FLIES (TABANUS SPP.), AND DEER FLIES (CHRYSOPS, HAEMATOMATA, AND PANGONIA SPP.)**

Horse flies, march flies or breeze flies, and deer flies are large, robust, blood-feeding flies that are widespread in both temperate and tropical regions. Only the females take blood meals, but the bites are savage and cause significant distress to large animals, particularly horses and cattle. These flies can act as mechanical vectors of diseases caused by viruses (equine infectious anemia, bovine leukosis, vesicular stomatitis, hog cholera), bacteria (anthrax, tularemia), and trypanosomes (surra). Eggs are laid on the leaves of plants growing in or near standing water. The larval and pupal stages occur in the water or mud, and the life cycle takes 4 to 5 months to complete. The flies are active in summer and attack animals principally on the legs and ventral abdomen. Duration of activity can be relative short (i.e., 3 to 4 weeks), but stress on the animals can be very high during that time. Fly attacks lead to bunching of animals with the attendant likelihood of overheating and in some cases resulting in animals stampeding through fences. Adult flies are attracted to host volatiles, including components of host urine. Control is difficult unless wet areas can be drained or livestock kept away from those areas where the flies are most active. Repellents have been used and are reasonably effective in horses subject to fly worry. The use of DEET affords protection for only a few days and is costly, but its use in milking cattle gives increased milk yield and butterfat.

Synthetic pyrethroid-impregnated eartags give very little protection against these flies.

**RECOMMENDATION**

Control is extremely difficult for both larvae and adults but should be attempted for the purpose of reducing effects of adult flies on animal welfare.

**HYPODERMA SPP. INFESTATION (WARBLE FLIES)**

Infestations of cattle with the larvae of *Hypoderma* spp. cause serious damage to hides and carcasses, in addition to production losses. Occasional deaths result from anaphylactic shock or toxemia and damage to the central nervous system or esophagus. Several other flies with very similar life histories affect goats (*Przewalskiana silenus*) and semidomestic reindeer (*Hypoderma tarandi*) in addition to affecting the wellbeing of wild ruminants. *Dermatobia hominis* larvae affect all species of ruminants and humans (tropical bot fly) in South America.

---

**SYNOPSIS**

**Epidemiology** Eggs attached to hair in spring to late summer, larvae penetrate skin and migrate to esophagus (*H. lineatum* and *H. sinere*) or spine (*H. bovis*), where they stay for 2 to 3 months; they then move to subdermal tissue along the back and after 2 to 3 months emerge from the breathing hole, fall to the ground, pupate, and emerge as adult flies 3 to 5 weeks later. Larvae of *P* and *H. tarandi* do not undergo migration within deep tissues of their host.

**Clinical signs** Reduced growth and production. Larvae in the back cause obvious swellings; larvae in the spinal cord may cause posterior paralysis. Treatment of larvae while they are in the esophagus may cause serious edema, and edema and paraplegia may occur if animals are treated when larvae are in the spinal canal.

**Clinical pathology** An enzyme-linked immunosorbent assay (ELISA) is available.

**Lesions** Larvae are found in discolored tissue.

**Diagnostic confirmation** Swellings along back characteristic.

**Differential diagnosis** Traumatic injury to the spine; aberrant *S. vulgaris* larvae in the horse.

**Treatment** Macrocyclic lactone endectocides.
ETIOLOGY
There are two species that specifically parasitize cattle: Hypoderma bovis and H. lineatum. A third species, H. sinense, affects cattle and yaks in central Asia. The adult flies are robust and hairy, about the size of a bee (12 to 18 mm long), are yellow-orange in color, and have two wings. They are not easily seen because of the rapidity of their flight.

Repeated infestation results in an acquired immunity that results in older animals being less severely affected than younger animals.

Horses are occasionally infected with Hypoderma species of cattle. The larvae are found in subcutaneous cysts on the back, but they have not been reported to complete development. This location causes problems if they are in the saddle region.

Losses to the cattle industry caused by warble fly have not been estimated recently, but in 1965 the loss was estimated to be US$192 million per annum in the United States, and in 1976 approximately $100 million. In 1982 the cost of warble fly was estimated as £35 million for Great Britain, but the parasite has now been eradicated from the United Kingdom and Ireland.

Advent of the macrogryclic lactone endectocides has greatly reduced the prevalence of the cattle species in North America, but they persist in localized areas.

Hypoderma tarandi, H. acteon, and H. diana infect reindeer/caribou and deer. H. diana is found throughout Europe in several deer species but may also occur in sheep. H. actaeon, also found throughout Europe, is known only from the red deer. These species do not undergo deep tissue migrations that characterize the life cycle of the cattle species.

Przhevalskiana silenus is similar to the previously described species and is a parasite of goats in the Mediterranean basin, parts of eastern Europe, Pakistan, and India. This species also does not have a deep tissue migration, and larvae tend to develop subcutaneously very near the site of initial skin penetration. The losses resulting from this parasite are significant and result from reductions in carcass quality and reduced animal health.

The larvae of Dermatobia hominis, a small (12 mm long) related fly, parasite a wide variety of hosts and cause major economic losses to cattle production in South America. They also affect humans and are a major zoonosis for travelers in the region. Mature larvae are about 2.5 cm long and develop in a subcutaneous cyst that can be quite painful. Female Dermatobia oviposit on zoophilous, “porter” flies such as mosquitoes and stable flies, which they catch on the wing. The eggs are transported to the mammalian host, and they hatch in response to increased temperature as the fly lands. Larvae penetrate the skin, but do not migrate. Treatment and control measures are the same as for Hypoderma spp. of cattle.

LIFE CYCLE AND EPIDEMIOLOGY
Warble flies historically were common parasites of cattle in the northern hemisphere, including North America and Europe, and are common in parts of Asia. The distribution of these parasites has been changing recently with the widespread use of macrocyclic lactone endectocides and the adoption of eradication programs in many European countries. Infestations south of the equator are rare and are the result of imported cattle, although endemic cases have occurred in Chile.

Adult flies are active in the spring to late summer, with H. lineatum usually appearing 3 to 4 weeks before H. bovis. H. lineatum attaches up 600 eggs, in strings of 5 to 25, to hairs on the legs or lower parts of the body, whereas H. bovis attaches eggs, one at a time, to hairs on the rump and upper parts of the hindleg. The oviposition flight of H. bovis, darting in to lay each egg, will terrorize cattle. Eggs hatch in 4 to 6 days. The larvae penetrate the skin using protease enzymes and migrate through connective tissues to reach the esophagus (H. lineatum) or the epideral fat in the spine (H. bovis), where they stay, feeding and growing, for 2 to 4 months. They subsequently continue their migration to reach the subdermal tissue of the back in the early spring. Here they make a breathing hole and become encased in a granulomatous cyst. They complete development in 1 to 2 months, passing through second and third instars, and emerge through the hole, fall to the ground, and pupate. Adult flies emerge some 3 to 5 weeks later. The fully developed larvae are thick and long (25 to 30 mm), light cream in color, but darkening to almost black as mature third instars. A single animal may have up to 300 larvae, each developing with granulomatous cysts, with breathing holes, under the skin of the back.

Hypoderma tarandi females deposit eggs on the hair of reindeer or caribou, and larvae hatch in approximately 7 to 10 days. Larvae penetrate the skin close to where the eggs are deposited and do not migrate into deep tissues. Flies are active during arctic summer, and larvae remain in the back until early spring.

Przhevalskiana silenus eggs are attached to host hairs, and the larvae hatch after 7 to 8 days. Larvae penetrate the skin in the area where they were deposited, where they remain throughout their development period. Flies are known to be active from May through June in southern Italy and can be found in host tissues from May through the following February.

The timing of the life cycle, that is, the period when grubs are present in the animals and the time at which the flies are present in large numbers, varies with the climate and is of importance in a control program. H. lineatum generally is 1 to 2 months ahead of H. bovis, and where the two flies are present, both “grub” and “fly” seasons may be very long. In the southern United States the fly season is February and March; in Canada it is June to August.

The period when grubs are present in the back is December in the south and February to May in Canada. In Europe the larvae begin to move to the back from January to July.

PATHOGENESIS
Migrating first instars cause little damage as they use their proteolytic enzymes to migrate through connective tissue. The enzymes, however, have an antiinflammatory effect, partially through cleavage of complement components. Larvae maturing under the skin of the back form holes in the skin, and the reaction of the host encloses each grub within a granulomatous cyst. On rare occasions an anaphylactic reaction may occur in a sensitized animal as the result of death of migrating larvae; chance migration into the brain may also occur. Intracranial myiasis as a result of H. bovis has also been recorded in the horse. Treatment of animals when the first instars are in the esophagus may cause a massive inflammatory edema that may prevent feeding and swallowing of saliva; eructation may stop and bloating may occur. Treatment of H. bovis while it is in the spinal canal may also cause edema and mild to severe paraplegia.

CLINICAL FINDINGS
Cattle at pasture may be worried by adult fly attacks that disrupt grazing and breeding behavior, which are exacerbated when fly populations are large. Avoidance behavior, called gadding, may result in injury as cattle run into fences and other natural obstructions. Heavy infestations with larvae are commonly associated with poor growth, poor body condition, and production losses, but such heavy infestations are often complicated by other forms of mismanagement, including malnutrition and parasitic gastrointestinal enteritis. Immunosuppression results from the effect of larval secretions. Infected cattle milk poorly, and a considerable increase in milk production and milk fat occurs after treatment.

The presence of the subcutaneous larvae causes obvious swelling, with pain on touch. The swellings are usually soft and with an opening that is usually evident. There may be as many as 200 to 300 such lesions on the back of one animal.

With involvement of the spinal cord there is a sudden onset of posterior paralysis without fever and without other systemic complications.
signs. The suddenness of onset and the failure of the disease to progress usually suggest traumatic injury. A similar disease can occur in horses and is reputed to be more common in horses than in cattle.

**CLINICAL PATHOLOGY**

An ELISA that detects antibodies to the secreted enzymes of *H. lineatum* and *H. bovis* has been developed. It has been used in monitoring the eradication program in Great Britain and in France. In addition, an antigen-capture ELISA, used to detect the presence of circulating quantities of the predominant larval enzyme, has been developed. This will be useful in differentiating active from cleared infestations and will be useful in detailed surveillance programs if used at the correct time in the life cycle.

**NECROPSY FINDINGS**

The first instars, migrating within connective tissue, are usually surrounded by a zone of yellow-green discoloration. Later larval stages lie in a subcutaneous, granulomatous cyst that may contain a pale fluid. Rarely the cyst will contain a large amount of purulent discharge. Other characteristic findings include the following:

- No other disease causes the characteristic swellings on the back.
- The differential diagnoses of posterior paralysis and anaphylaxis are discussed in detail under the respective headings of “Disease of the Spinal Cord” and “Anaphylaxis.”
- The clinical signs of macrocytic lactone poisoning have not been reported to cause these symptoms.
- Posterior paralysis as a result of destruction of the larvae in the epidermal space usually occurs, but macrocytic lactone products have not been reported to cause these symptoms.

**TREATMENT**

Macrocylic Lactone Compounds

All larval stages of cattle grubs and other oestrid flies are very sensitive to macrocytic lactone endectocides. Their widespread use in nematode control programs plays a major role in controlling warble flies. Their residual activity will persist for about 4 weeks.1,5

**Treatment Recommendations**

Treatment with a macrocytic lactone-based product is strongly advised, both to increase productivity and to maintain population control.

**Manual Removal**

When small numbers of cattle are affected with relatively few warble grubs, manual removal of the larvae during removal may cause a severe systemic reaction. This reaction and the one that sometimes occurs after systemic treatment of cattle infected with cattle grubs has been ascribed to anaphylaxis. However, there is evidence that it a direct result of toxins liberated from dead maggots and that phenylbutazone may control this toxin. The clinical signs include dullness, salivation, lacrimation, dyspnea, wrinkling of skin on the side of the neck, and edema under the jaw.

**CONTROL**

With the macrocytic lactone endectocides, in general, systemic treatments are given at the end of fly activity and in the spring after first instars have left sensitive tissues. In those species that do not undergo deep tissue migration, treatment can be instituted anytime after the cessation of fly activity.

Cattle grub has been eradicated in Norway, Sweden, Denmark, Malta, Ireland, and Great Britain. Eradication programs were initiated in France. Surveillance has decreased in most countries as a result of the excellent efficacy of the macrocytic lactone products. However, evidence from Canada suggests that residual populations remain.1 A joint Canadian–U.S. study using sterile male *Hypoderma* species eradicated these species from the test area, but the difficulty of mass rearing system, makes this technique impractical for large-scale warble fly control.4

Vaccination of cattle using crude larval extracts has reduced both the number of warbles in the back and the number of larvae that could pupate.5 Results of vaccination studies with recombinant antigens have been variable, and commercial development has ceased. Use of antigens derived from “hidden” sites such as the fatbody have produced excellent results,5 and potential components have been identified, but further work has not been followed up.6 Sequencing of the mitochondrial genome of *H. lineatum* has been completed.7

**REFERENCES**

**HORN FLIES AND BUFFALO FLIES (HAEMATOMBIA SPP)**

**ETOLOGY**

The small (6-mm) grayish flies of the *Haematobia* species, known as horn flies and buffalo flies, have distinct geographic distributions, *H. irritans exigua* in Australia and South East Asia, *H. irritans irritans* throughout North and South America and Hawaii, and *H. minuta* in Africa. *H. irritans irritans* is common in Europe, where it causes few problems. This species was transported to North America in the late 1800s, where it rapidly established and spread. It has subsequently moved into South America, where it has also become a major problem. *Haematobius* species are known as vectors for the nematodes *Stephanofilaria stilesi*, but their impact is thought to be of little importance.

**LIFE CYCLE AND EPIDEMIOLOGY**

These insects have a typical fly life cycle and habits. Eggs are deposited away from the animal onto freshly deposited dung, where the larval stages develop in a high temperature-regulated manner. The onset of diapause in the pupal stage is regulated at this stage and requires that the larvae be exposed to increased hours of low temperatures for the pupae to become diapause driven. Three larval stages are spent in the dung, with larvae feeding largely on bacteria. Pupae form in the dry regions outside of the dung pat. Both sexes of these flies are obligate blood feeders, primarily attacking pastured cattle and water buffalo. They do not survive off the host, other than for short periods. They are not known as vectors for any disease agents other than the nematodes *Stephanofilaria* spp. They cause significant reductions in productivity of pastured cattle through induction of stress, changes in grazing patterns, and, in extreme cases, blood loss. Burdens of 200 to 500 flies will reduce weight gains of beef cattle (up to 14% reduction) and milk yield of dairy cows. Heavy infestations (over 1000 flies) can cause serious loss of condition and, rarely, deaths. Control results in higher feed efficiency, increased growth rate, and increased calf-feeding weights.

The flies are easily recognized by the way in which the wings are held at rest, slightly divergent and angled upward, away from the body. Adult flies stay on the host most of the time, unless disturbed. Females leave the host, as feces are passed, to deposit eggs around edges of the freshly deposited dung. Larvae develop within the dung pat, feeding primarily on bacteria. Development is regulated by environmental temperatures, and the larvae are stimulated to enter diapause (arrested development) if temperatures become too low. Mature larvae exit the dung to pupate in the dry soil below and around the pat. A complete life cycle may require up to 3 weeks under optimal environmental conditions. Thus at higher temperatures in excess of 15 generations may be produced in a single season; in more temperate climates such Canada and the upper United States, only 5 generations may occur.

**PATHOGENESIS**

The flies congregate chiefly on the withers, shoulders, and flanks and around the horns and eyes. Flies take numerous (15 to 20) small blood meals per day. In North America
feeding often takes place on the ventral midline and several 2- to 5-cm-diameter feeding lesions are often observed. Zebu cattle are less affected by the flies than British breeds, and although they may carry large populations of flies, they show fewer feeding lesions.

CLINICAL FINDINGS
Whereas adults rarely leave the host except for oviposition, the newly emerged flies of *H. irritans irritans* will travel up to 20 km in search of new hosts. They may be dispersed also by prevailing strong winds, and they are carried long distances by the movement of cattle to new pastures. The distribution of *H. irritans exigua* is controlled by environmental factors, particularly temperature and humidity. At temperatures below 21°C (70°F), the flies become sluggish, and at 5°C (41°F) they become comatose.

TREATMENT AND CONTROL
Infestations have been controlled by traps, insecticide sprays, back rubbers, dust bags, or eartags impregnated with insecticides. Traps have been designed for use with dairy cattle that walk through them on their way to and from the dairy. The flies are dislodged by gauze strips and are retained in the trap and killed when they rest on the insecticide-coated walls. Traps are rarely used today, but recent work with modified traps has given 80% to 90% control.

Back rubbers consist of absorbent material, impregnated with insecticide or oil, wrapped around a cable or chain suspended from a central pole and attached to ground-level supports or as a cable suspended a little over a meter above the ground between two level supports or as a cable suspended a little from a central pole and attached to ground-wrap around a cable or chain suspended. Impregnated eartags controlled units of insecticide as it spreads from calves to cows. Flies can also be controlled by dipping, but this technique is rarely used solely for flies. Current products are combined with synthetic pyrethroids to extend the protective period. In areas where cattle ticks require regular treatment, adequate control of flies may be gained incidentally, but if treatments are not effective cattle can be oversprayed with pyrethroids. Some research on control in North America using essential oils has been conducted, and the microbiome has been sequenced.

Macrocyclic lactone endectocides are highly effective against larval horn flies and the larvae of face flies, stable flies, and houseflies, often killing larvae for periods in excess of 8 weeks. However, in terms of practical control, where flies immigrate from surrounding herds, the duration of efficacy is not more than 2 weeks. In addition, the macrocyclic lactones generally cause significant reductions of nontarget insects in the dung community, many of which are beneficial because they are natural enemies of the horn fly and buffalo fly. The various macrocyclic lactone products have differential effects on flies and other dung insects, and it appears that moxidectin has the least impact. Virtually all of the cattle on pasture in North America are affected by horn flies, with the exception of those kept at higher elevations. The effect will be altered by various factors, including both physical and biological characteristics of the flies and their hosts.

Four-on formulations of pyrethroids are highly effective, as evidenced by application of 1% cyfluthrin. Insect growth regulators (e.g., Diflubenzuron) applied as a bolus gave 80% control of the immature stages of the face fly and horn fly in the manure for at least 20 weeks and reduced the number of dung beetles for 7 weeks. A 3% methoprene bolus was also active against flies but had no apparent effect on the dung beetles. The use of essential oils has been shown to have good fly control, but their use requires further testing.

RECOMMENDATION
Treatment is necessary to keep populations below the economic threshold and to prevent this from becoming an animal welfare issue.

BLACK FLIES, BUFFALO GNATS (SIMULIIDAE)
These small gray to black flies (5 mm) are members of the family Simuliidae and include a number of species and genera. The important flies appear to be *Cepheia pec-urum*, which is common in the southern states of the United States; *Simulium arcti-
several species under control. An electrostatic sprayer that allows efficient application of repellents or insecticides to cattle under pasture conditions can be used. The insecticide or repellent solution is dispersed as charged droplets that are attracted to the hair of the animals.

**HOUSEFLY (MUSCIDAE—** **MUSCA DOMESTICA**)

The common housefly has a worldwide distribution and is of veterinary importance because it is capable of transmitting, in a mechanical manner, the causative bacteria of many infectious diseases. It is often cited as a means whereby anthrax, erysipelas, and brucellosis are spread, but its importance in this regard is largely unproven. Houseflies are intermediate hosts for the larvae of Haloroma muscae and Draschia megastoma. The eggs are laid in decaying organic matter of any kind. Larval development is temperature dependent, and a life cycle may be completed in 12 to 14 days so that in warm, wet summers the fly population may increase very rapidly, causing annoyance to livestock and farm workers.

Housefly population management requires frequent and thorough removal of manure and other rich organic matter. In dry weather the manure can be spread thinly on fields, but a more dependable method is to place it in a special fly trap (e.g., Baber’s fly traps), from which larvae and adult flies cannot escape. Chemical treatments to control flies require application to resting sites on buildings and other facilities or the placement of baits containing methomyl, ethoprophos, naled, or dichlorvos at appropriate locations. Development of insecticide resistance can occur rapidly, and there are numerous examples of resistance to multiple classes of insecticide at a single location. Rotational use of insecticide classes is absolutely essential in the management of resistance.

Management of housefly populations can be augmented through release of parasitic wasps (family Pteromalidae) that kill pupae. Where thousands of wasps are released at sites on buildings and other facilities or the placement of baits containing methomyl, ethoprophos, naled, or dichlorvos at appropriate locations. Development of insecticide resistance can occur rapidly, and there are numerous examples of resistance to multiple classes of insecticide at a single location. **BUSH FLIES (MU** **SCA V** **ESTUTISSIMA**

Bush flies occur commonly in Australia in drier areas and are a cause of stress to livestock in the summer months. Bush flies die out in southern Australia each winter, but breeding continues in the north, and the regular northern winds that commence about September each year blow flies southward, which then repopulate the areas that are now suitable for reproduction. Larvae usually develop in fecal matter from several source animals. Adult Musca vetustissima occur in very large numbers and during the day congregate around the eyes, on the lips, on any visible mucous membrane, and on wounds to obtain moisture. They are thought to carry contagious ophthalmia of sheep, infectious keratoconjunctivitis of cattle, and contagious eczema of sheep; to delay the healing of wounds; to contribute to the lesions produced by buffalo flies (Haematobia irritans exigua); and to act as intermediate hosts for the larvae of Draschia megastoma, Habronema muscae, and Thelazia spp. Control of the fly population is virtually impossible in the areas where it occurs, but individual animals may be protected by repellents such as dimethyl phthalate or DEET. Sprays containing 1% of dichlorvos are effective but must be applied daily. Dung beetles, introduced from Africa, break up dung pats, which aids in control of larval stages and in reducing fly numbers. The bush fly has been implicated in the dissemination of several food-borne pathogens that can have serious concerns.

**RECOMMENDATION**

Control of adults is recommended to alleviate animal welfare concerns.

**REFERENCE**

**FACE FLY (** **MU** **SCA AUTUMNALIS**

This medium-sized fly, similar in appearance to the housefly but having an olive abdomen and yellow wing bases, is found in the United Kingdom and Europe. It is a nonbiting muscid fly that swarms around animals and humans from late June to September. Larval development is in soil and litter, and generally there is only one life cycle per year. The lesions on sheep are self-inflicted trauma in attempts to alleviate fly irritation. Sores are often large and open, and they may be made more severe by bacterial invasion. The wounds may predispose to blowfly strike by Lucilia sericata. The pathogens of summer mastitis of cattle can be spread mechanically by this fly as well as a number of related muscid flies, and Trueperella (Actinomyces or Corynebacterium) pyogenes has been shown to persist in H. irritans for up to 4 days.

Control is difficult and is similar to that used for the other nonbiting muscid fly, M. autumnalis. Eartags impregnated with 8.5% cypermethrin or 10% permethrin reduce the severity of fly damage in sheep, and tagged ewes give protection to their lambs. However, it is likely that resistance will quickly occur in the same manner as in the face fly. Head caps are most effective but are tedious to apply.

**REFERENCE**

**BITING MIDGEs (CERATOPOGONIDAE)**

These tiny flies (1-3 mm long) are members of the family Ceratopogonidae, of which the most important genus is Culicoides. These flies are blood feeders and induce stress in hosts, and they can transmit infectious diseases such as bluetongue in sheep, horse sickness, and ephemeral fever in cattle. They are also intermediate hosts for nematodes of the genus Onchocerca. Because of their importance as vectors of arboviruses, studies have been done on their feeding habits. Cattle and sheep are the most common hosts attacked, but some species also feed on birds or dogs. Hypersensitivity to the bites of Culicoides spp. results in an allergic dermatitis (sweet itch) in horses in Australia and North America and is discussed elsewhere. Cattle also show considerable irritation during attacks by large numbers of midges. They react with vigorous stamping of the feet, switching of the tail, and continuous movement.

The flies are plentiful in the warmer months and are most active at dawn and dusk. Because of their small size they are capable of being carried long distances by wind. Larvae develop in rich, high-organic-matter sites with high moisture content. Control of the larvae and of flies is virtually impossible, and most measures to reduce their importance are based on preventing access of the flies to the animals. Repellents, especially dimethyl phthalate or DEET, are effective on a short-term basis. Antihistamines can be used regularly but are too expensive for general use. Keeping horses away from areas where the flies are present in large numbers is advisable. Backline pour-on treatment of horses with 4% high-CIS permethrin every 3 weeks gave a good response in 86% of horses. Ivermectin at the recommended dose of 0.2 mg/kg would not produce the serum concentration that would have noticeable effects on blood-feeding C. variipennis. Recently, modeling of changing weather patterns indicates that such patterns may alter the distribution of important vectors and thus alter the influence of diseases.

**REFERENCES**

**MOSQUITOES (CULICIDAE)**

A number of mosquitoes, including Psorophora, Aedes, Mansonia, Culex, and Anopheles spp. are important parasites of domestic animals. When the blood-feeding females are present in large numbers, they cause stress to animals and have been known to kill young pigs and puppies by the severe anemia they produce. Although such occurrences are rarely recorded, the blood loss that can occur in severe infestations is surprising. The stress associated with mosquito attack is sufficient to cause reductions in efficiency; even in mature large animals.

Their most important role is as vectors of disease. Culex tarsalis, Aedes dorsalis, and Aedes nigromaculis transmit equine encephalomyelitis. Culex tritaeniorynchus is the principal vector of Japanese B encephalitis in Japan. Various Culex species vector western equine encephalitis, eastern equine encephalitis, and West Nile virus. These viruses can have serious effects on unprotected horses and are transmissible to humans via mosquito bites. Vaccines are available to protect against all of these arboviruses. Psorophora confrinis is instrumental in spreading the eggs of Dermatobia hominis, the tropical warble fly; and Mansonia spp. transmit Rift Valley fever. The filarial worm Setaria digitata is also spread by mosquitoes.

Control over a large area must include drainage of collections of still surface water or destruction of the larvae by the addition of any one of a number of insecticides. For small groups of animals, protection from the attacks of mosquitoes can only be satisfactorily effected by mosquito-proof screens. Temporary protection by repellents such as dimethyl phthalate is only partial. Permethrin, 100 mL of a 0.5% emulsion, applied with an electrostatic sprayer provided greater than 70% protection for at least 72 hours.

**Tick Infestations**

**SYNOPSIS**

**Etiology** Many species of ticks act as vectors of disease or cause death from anemia; others cause paralysis. Heavy burdens cause loss of production.

**Epidemiology** Life cycles vary widely both in the number of hosts required and the host specificity. Animals are infested by larval or nymphal stages on the ground.

**Clinical signs** Anemia, paralysis, tick fever, and tick worry.

**Clinical pathology** Ticks obvious on clinical examination. Blood smears for tick fevers (Babesia, Theileria, and Anaplasmia).

**Lesions** Skin damage as a result of biting and rubbing; anemia. See other chapters for lesions as a result of diseases transmitted by ticks.

**Diagnostic confirmation** Ticks easily found, should be identified as to species.

**Treatment** Dipping, spraying, application of pour-ons and injectable acaricides.

**Control** Regular treatment at intervals dependent on the life cycle of the tick, pasture spaying to destroy free-living stages, the use of resistant cattle, and vaccination all play a part.

**Tick infestations are of great importance in the production of animal diseases, particularly in livestock housed in tropical and sub-tropical areas. In addition to their role as vectors of infectious diseases, as outlined in the following discussion, heavy infestations can cause direct losses. Many ticks are active blood feeders and may cause death from anemia. Some species cause tick paralysis, and it is possible that other ticks may elabo-rate toxins other than those causing paralysis. Heavy tick burdens cause sufficient irritation and stress such that affected animals become anorexic, which may lead reduced productivity. One tick, Boophilus microplus, is reported to affect in excess of 75% of the world cattle population. The economic impact has been estimated at US$7 per animal per year, and in Brazil, which has the fifth largest cattle herd, the losses estimated at US$2 billion per year. Ticks are divided into two groups: Argasidae (soft-body ticks) and Ixodidae (hard-body ticks). The life cycles of the ticks vary widely. Some species pass their entire lives on one host, others pass different stages of the cycle on successive hosts, and others are parasitic only at certain stages. The eggs are laid in the soil, and larvae attach themselves to a passing host, on which they may develop through one or more nymphal stages before becoming adults. Adult females engorge on blood or lymph and drop to the ground to lay their eggs. One-host ticks are more easily controlled than those that pass part of their life cycles away from the host. A list of the single- and multiple-host ticks is shown in Table 16-5.

Although many ticks favor a particular host, they are usually not completely host-specific, and many parasite a wide variety of animals.

**Diagnostic confirmation** Ticks easily found, should be identified as to species.

**Treatment** Dipping, spraying, application of pour-ons and injectable acaricides.

**Control** Regular treatment at intervals dependent on the life cycle of the tick, pasture spaying to destroy free-living stages, the use of resistant cattle, and vaccination all play a part.
of animals. In the limited space available here, the species are listed according to whether they transmit bacterial, viral, or rickettsial diseases of livestock or only cause worry. Ticks that transmit economically important protozoan diseases of livestock, such as babesiosis and theileriosis, are discussed in Chapter 11 (Table 11-7). Ticks that cause paralyzation and other neurologic signs are discussed in Chapter 15.

**Bacterial, Viral, and Rickettsial Diseases Transmitted by Ticks**

The transmission of diseases associated with these agents may be effected by means other than ticks. *Anaplasma marginale* can be spread by biting flies if large numbers are present when the animals are experiencing a heavy parasitemia. Outbreaks of anaplasmosis can also occur following the use of heavy parasitemia. Outbreaks of anaplasmosis are easily caused by blood transfusion, castration, or blood sampling, and anaplasmosis can also occur following the use of these agents may be effected by means other than ticks. *Anaplasma ovis* and *Dermacentor marginatus* are listed in Table 16-6. Transmission of *Anaplasma* may be transovarially, with one stage becoming infected and a subsequent stage passing the infection to a new host, or ticks may transmit infection within the one stage if they detach and feed on a new host.

**Ticks That Cause Direct Losses**

Ticks cause damage to hides and loss of production, anemia, and death when they are present in large numbers. They also cause greater morbidity and mortality during periods of drought, in addition to delays in fattening, resulting in animals held longer before they can be sold. Ticks that have this effect on production but are not known to cause paralysis or transmit infectious diseases in farm animals are as follows:

- *Otozius megini*—the “spineo ear tick” of the United States and Canada
- *Amblyomma americanum*—the “Lone Star tick” of the United States
- *A. maculatum*—the “Gulf Coast tick” of the United States
- *Margaroapis winthemi*—of South America and Africa
- *Olmithorouus moubata*—of Africa and Southeast Asia
- *O. savignyi*—of Africa and Southeast Asia
- *Haemaphysalis longicornis*—of Australia and New Zealand.

**TREATMENT AND CONTROL OF TICK INFESTATIONS**

Four methods are now available to treat and control tick infestations, with the primary role continuing to be played by chemical acaricides:

- Administration of acaricidal agents
- Pasteurization management
- Use of resistant cattle
- Vaccination

**Acaricidal Agents**

Individual animals can be effectively treated by the application of any one of a number of acaricides applied either as a spray or by dipping. The choice of acaricide for treatment depends largely on three factors:

- The persistence of the compound on the skin and hair coat
- The likelihood of residues toxic to humans appearing in the milk or meat
- Whether or not the ticks in the area have developed resistance to the particular acaricide

Arsenicals, in the form of water-soluble arsenic salts, have been widely used to treat tick infestations but are no longer used in many parts of the world because of resistance, toxicity, and environmental concerns.

</table>
Chlorinated hydrocarbons replaced the use of arsenicals but have been withdrawn from most markets because of high toxicity and long duration of effect. Resistance to chemical acaricides, including macrocyclic lactones, has become a major issue for the effective management of one cattle tick, *Boophilus microplus*. In many cases cross-resistance between chemical families occurs, further complicating the use of rotational schemes aimed at managing the development and degree of resistance.

The same criteria apply in control as in treatment except that cost becomes a limiting factor when large numbers of animals require frequent treatments, and it is obvious in some circumstances that the effect of tick infestation on Brahman-cross steers is insufficiently great to warrant treatment. It is impossible to make specific recommendations on methods of application and the most efficient insecticide to use because these vary widely between species of ticks. However, whenever possible, treatment should be given systematically in a program based on the life cycle and epidemiology of the tick. A number of treatments may be used early in the tick season to prevent the increase in tick numbers. Care must be taken in areas where tick fever also occurs, so as not to disrupt the transmission of the tick-fever organisms and leave the cattle susceptible to later infection. Other special cases include *Otodis megnini*, the nympha of which drop off to molt and lay eggs in protected spots, necessitating the spraying of buildings, fence posts, feed troughs, and tree trunks in feedlots where heavy infestations are most common. *Omnithodorus* spp. ticks are difficult to control because the nymphs and adults attach to feed for brief periods only. Where ticks that cause paralysis are common, it may be necessary to apply an insecticide as a dust and dip at short intervals.

**Organophosphates**

The organophosphates as a group are effective, but tick strains resistant to many of them have appeared. Other drugs in current use include dioxathion, diazinon, carbophanthion, coumaphos, ethion, bromophos-ethyl, chlorpyrifos, and phosmet. Pour-on applications of chlorpyrifos and phosmet have been tested but were not as effective as spray applications. Addition of acaricides to the feed has also been tried but has not been successful, whereas ear tags impregnated with tetrachlorvinphos did not give satisfactory control and increased the risk of development of resistance to the drug.

Preparations vary in the duration of the protection they afford, and local conditions of rainfall and tick population must be taken into account when determining the time intervals between sprayings or dippings. A special case is that of young lambs that are exposed to tick pyemia. Sprays, dips, and ointments are too toxic, and the most effective procedure is the application of a liquid emulsion cream containing the insecticide to the wool-less parts of the body. Chlorpyrifos 0.48 kg/ha markedly reduces the number of ticks on the pasture, but it is too expensive for routine use.

**Pyrethroids**

Amitraz, a formamidine, and the synthetic pyrethroids have been used widely in Australia and have proved to be effective, active against organophosphate-resistant strains, and safe. In a study in the United States, 0.025% amitraz applied as a whole-body spray or by dipping gave 86.0% or 99.8% control, respectively. Ticks resistant to DDT are also resistant to the synthetic pyrethroids, and to overcome resistance pyrethroids can be combined with an organophosphate. Successful combinations in Australia are cypermethrin plus chlorfenvinphos and deltamethrin plus ethion. A synthetic pyrethroid, flumethrin, has been marketed by itself at higher use concentrations for both plunge dipping and as a pour-on treatment. As a 1% pour-on, 1 mL per 10 kg body weight gave 97% efficacy, and 0.0033% as a spray gave 99% efficacy and acted more quickly. The efficacy of synthetic pyrethroid-impregnated ear tags has been reported, but these are likely to lead to resistance. Cyhalothrin also controls multiresistant strains and is used in plunge dips.

Bioassay results show lambdachlorothrin to be as effective as chlorthrin as a whole-body spray, although the 1% pour-on was less than 50% effective. Resistance to all pyrethroids has been reported. Three pyrethroid acaricides have been shown to markedly reduce the hatching of eggs. Permethrin 0.1% or cypermethrin and cyfluthrin 0.05% could be useful in cleansing and disinfecting premises.

**Macrocyclic Lactones**

Ivermectin given subcutaneously gives satisfactory control of *Boophilus microplus* for 21 days following an initial lag period of 2 days. As little as 0.015 mg/kg per day gives complete control and raises the possibility of a slow-release subcutaneous implant. Two treatments of 0.2 mg/kg at 4-day intervals is considered satisfactory in cleansing cattle under field conditions. However, ivermectin may not be effective against *Ixodes ricinus*, but a slow-release bolus active for 90 days did give good control of a variety of ticks. If given topically, 0.5 mg/kg was required to reach the efficiency achieved by 0.2 mg/kg subcutaneously.

Moxidectin 0.2 mg/kg subcutaneously at 4-week intervals or 0.5 mg/kg as a pour-on along the back gives good protection against *B. microplus* resistant to organophosphorous insecticides and DDT, and each treatment has a rapid knockdown effect on populations of buffalo fly after treatment. Doramectin 0.2 mg/kg SC is highly efficacious in removing *B. microplus* and preventing reestablishment. Closantel 22.2 mg/kg orally to cattle (greater than the typical oral dose) was shown to disrupt the life cycle of *Rhipicephalus appendiculatus*; those that oviposited laid few eggs, and most of these did not hatch. Few larvae or nymphs molted.

Ticks in the ears of horses should be treated by the insertion of a few drops of an oily acaricidal preparation.

**Use of Resistant Cattle**

It is possible to reduce the impact of ticks and tick-borne diseases by the introduction of Brahman and Brahman-cross cattle, which are more resistant than British breeds and African cattle. The resistance has been shown to be largely acquired, and it is mainly expressed against the larvae in the first 24 hours after attachment. In Australia the possibility that *B. microplus* might escape from its control area because of increased resistance to acaricides has been realized. For this reason a great deal of attention is being paid to the possibility of selecting cattle for tick resistance. In most tick-infested areas, cattle should have up to 50% *Bovis indicus* breeding because this allows for a reduction in the frequency of treatments. Penalties such as reduced live-weight gains, late maturity, and poor temperament become evident when cattle have more than 50% *B. indicus*. With successive infestations cattle differ in their response to *B. microplus*. Thus there is increased irritation and more licking and a decrease in the number of ticks carried. Resistance to ticks has been shown to be related to skin thickness and other factors and is heritable. Selection for tick resistance does not affect milk production.

**Pasture Management**

Measures other than the application of acaricides used in the control of tick infestation include burning of pasture, removal of native fauna, and plowing of fields. So little is known of the bionomics of specific ticks in specific areas that these measures have been largely unsuccessful, and it is impossible to provide details for their proper implementation.

In contrast, pasture spelling and rotational grazing are capable of greatly reducing the tick population on farms in some areas. If cattle are placed on spelled pastures early in winter when the ticks are producing few or no progeny and then alternated at 4-month intervals, the tick population can be controlled with a markedly lower number of treatments. The practicability of the procedure depends on a full-scale financial assessment of the increased weight gains relative to the costs of management. Duration of the spelling period varies between 2 and 3 months in summer to 3 to 4 months in the winter, but these intervals need to be
Diseases

ERADICATION

In most countries all that is attempted is reduction of the tick population by periodic dipping or spraying. Complete eradication is extremely difficult because of the persistence of ticks, especially multihost ticks, on wild fauna and the ability of adult ticks to live for very long periods away from a host. On the other hand, continuous treatment to restrain the tick population is highly conducive to the development of resistance, a problem that has become apparent in many tick areas. *Boophilus annulatus* was eradicated from the southeastern United States by a program of continuous dipping at short intervals of all livestock in the area. *B. microplus* was also eradicated from Florida by a similar procedure, but 20,000 deer, the important alternate host in the area, had to be slaughtered. Concern has been expressed that deer and other wildlife species may threaten efforts to prevent *B. microplus* and *B. annulatus* from becoming reestablished in the southern United States after they are introduced from Mexico. Attempts to eradicate other single-host ticks in other countries generally have not been successful.

Although both dipping and spraying are recommended for the control of ticks, complete wetting of the animals, which can only be effected by dipping, is essential if eradication is to be undertaken. This adds another impediment to eradication plans because of the cost of constructing proper dips and yards. When one considers that dipping may have to be carried out every 14 days for 15 months, that every animal in the eradication area must be dipped, and that a strict quarantine of the area must be maintained, it is obvious that eradication cannot be undertaken lightly.

ETIOLOGY

Pigs

A zinc deficiency in young, growing pigs can cause parakeratosis, but it is sometimes not a result of a simple zinc deficiency. Rapidly growing pigs have a high requirement for zinc in the diet. The availability of zinc in the diet is adversely affected by the presence of phytic acid, a constituent of plant protein sources such as soybean meal. Much of the zinc in plant protein is in the bound form and unavailable to the monogastric animal such as the pig. The use of meat meal or meat scraps in the diet will prevent the disease because of the high availability of the zinc. Another unique feature of the etiology of parakeratosis in swine is that an excess of dietary calcium (0.5% to 1.5%) can favor the development of the disease, and the addition of zinc to such diets at levels much higher (0.02% zinc carbonate or 100 mg/kg zinc) than those normally required by growing swine prevents the occurrence of the disease. The level of copper in the diet may also be of some significance, with increasing copper levels decreasing the requirement for zinc. A concurrent enteric infection with diarrhea exacerbates the damage done by a zinc deficiency in pigs. Weaning can induce transient declines in the serum zinc concentration of piglets, and this can be prevented by oral supplementation with zinc oxide. The clinical importance of this decline is unclear.

Ruminants

A primary zinc deficiency resulting from low dietary zinc in ruminants is rare but does occur. Many factors influence the availability of zinc from soils, including the degree of compaction of the soil and the nitrogen and

ERADICATION

In most countries all that is attempted is reduction of the tick population by periodic dipping or spraying. Complete eradication is extremely difficult because of the persistence of ticks, especially multihost ticks, on wild fauna and the ability of adult ticks to live for very long periods away from a host. On the other hand, continuous treatment to restrain the tick population is highly conducive to the development of resistance, a problem that has become apparent in many tick areas. *Boophilus annulatus* was eradicated from the southeastern United States by a program of continuous dipping at short intervals of all livestock in the area. *B. microplus* was also eradicated from Florida by a similar procedure, but 20,000 deer, the important alternate host in the area, had to be slaughtered. Concern has been expressed that deer and other wildlife species may threaten efforts to prevent *B. microplus* and *B. annulatus* from becoming reestablished in the southern United States after they are introduced from Mexico. Attempts to eradicate other single-host ticks in other countries generally have not been successful.

Although both dipping and spraying are recommended for the control of ticks, complete wetting of the animals, which can only be effected by dipping, is essential if eradication is to be undertaken. This adds another impediment to eradication plans because of the cost of constructing proper dips and yards. When one considers that dipping may have to be carried out every 14 days for 15 months, that every animal in the eradication area must be dipped, and that a strict quarantine of the area must be maintained, it is obvious that eradication cannot be undertaken lightly.

ETIOLOGY

Pigs

A zinc deficiency in young, growing pigs can cause parakeratosis, but it is sometimes not a result of a simple zinc deficiency. Rapidly growing pigs have a high requirement for zinc in the diet. The availability of zinc in the diet is adversely affected by the presence of phytic acid, a constituent of plant protein sources such as soybean meal. Much of the zinc in plant protein is in the bound form and unavailable to the monogastric animal such as the pig. The use of meat meal or meat scraps in the diet will prevent the disease because of the high availability of the zinc. Another unique feature of the etiology of parakeratosis in swine is that an excess of dietary calcium (0.5% to 1.5%) can favor the development of the disease, and the addition of zinc to such diets at levels much higher (0.02% zinc carbonate or 100 mg/kg zinc) than those normally required by growing swine prevents the occurrence of the disease. The level of copper in the diet may also be of some significance, with increasing copper levels decreasing the requirement for zinc. A concurrent enteric infection with diarrhea exacerbates the damage done by a zinc deficiency in pigs. Weaning can induce transient declines in the serum zinc concentration of piglets, and this can be prevented by oral supplementation with zinc oxide. The clinical importance of this decline is unclear.

Ruminants

A primary zinc deficiency resulting from low dietary zinc in ruminants is rare but does occur. Many factors influence the availability of zinc from soils, including the degree of compaction of the soil and the nitrogen and
phosphorus concentration. The risk of zinc deficiency increases when soil pH rises above 6.5 and as fertilization with nitrogen and phosphorus increases. Some legumes contain less zinc than grasses grown on the same soil, and zinc concentration decreases with aging of the plant. Several factors may deleteriously affect the availability of zinc to ruminants and cause a secondary zinc deficiency. These include the consumption of immature grass, which affects digestibility; the feeding of late-cut hay, which may be poorly digestible; and the presence of excessive dietary sulfur. The contamination of silage with soil at harvesting can also affect the digestibility of zinc.

**EPIDEMIOLOGY**

**Pigs**
Parakeratosis in pigs was first recorded in North America in rapidly growing pigs, particularly those fed on diets containing growth promoters. The disease occurs most commonly during the period of rapid growth, after weaning and between 7 and 10 weeks of age. From 20% to 80% of pigs in affected herds may have lesions, and the main economic loss is a result of a decrease in growth rate. In general, the incidence is greater in pigs fed in dry lots on self-feeders of dry feed than in pigs with access to some pasture, which is preventive and curative.

A low level of dietary zinc intake during pregnancy and lactation of gilts can result in skin lesions, stressful parturition, and an increased incidence of intrapartum mortality of piglets and deleterious effects on neonatal growth.

It has been suggested that parakeratosis occurs because very rapidly growing pigs outstrip their biosynthesis of essential fatty acids, and when the diet is high in calcium the digestibility of fat in the diet is reduced at the same time. The net effect in rapidly growing pigs could be a relative deficiency of essential fatty acids.

**Ruminants**
There are naturally occurring cases in cattle, sheep, and goats. The disease is well recognized in Europe, especially in calves. It is common in some families of cattle, and an inherited increased dietary requirement for zinc is suspected. The inherited disease occurs in Friesian and Black Pied cattle and is known as lethal trait A46. Signs of deficiency appear at 4 to 8 weeks of age. The main defect is an almost complete inability to absorb zinc from the intestine; zinc administration is curative.

The disease in cattle has been produced experimentally on diets low in zinc, and naturally occurring cases have responded to supplementation of the diet with zinc. Calves remain healthy on experimental diets containing 40 mg/kg zinc, but parakeratosis has occurred in cattle grazing pastures with a zinc content of 20 to 80 mg/kg (normal 93 mg/kg) and a calcium content of 0.6%. There is also an apparently improved response in cattle to zinc administration if copper is given simultaneously. Parakeratosis has also been produced experimentally in goats and sheep.

Zinc nutrition may be involved in the immune responses of feedlot calves. When calves are stressed by transportation or challenged with the infectious bovine rhinotracheitis virus, they tend to have reduced feeders, higher dry matter intake, and less body weight loss when fed organic zinc and manganese sources than the corresponding oxide forms.

Outbreaks of the disease have occurred in Sudanese Desert ewes and their lambs fed on a zinc-deficient diet of Rhodes grass containing less than 10 mg/kg of zinc. The disease has also been diagnosed in mature sheep and goats, and the cause of the deficiency could not be determined. A marginal zinc deficiency, characterized by subnormal growth and fertility and low concentration of zinc in serum, but without other clinical signs, can occur in sheep grazing pastures containing less than 10 mg/kg zinc.

In Germany, skin lesions have occurred in alpacas and llamas with low-zinc and low-copper status. In the affected herd, the average serum zinc and copper levels were 0.17 and 0.49 µg/mL for alpacas and 0.22 and 0.38 µg/mL for llamas, respectively. The levels considered normal in llamas are 0.30 µg for zinc and 0.40 to 0.70 µg copper per mL.

**PATHOGENESIS**
The pathogenesis of zinc deficiency is not yet well understood. Zinc is a component of the enzyme carbonic anhydrase, which is located in the red blood cells and parietal cells of the stomach, and is related to the transport of respiratory carbon dioxide and the secretion of hydrochloric acid by the gastric mucosa. Zinc is also associated with RNA function and related to insulin, glucagon, and other hormones. It also has a role in keratinization, calcification, wound healing, and somatic and sexual development. Because it has a critical role in nucleic acid and protein metabolism, a deficiency may adversely affect the cell-mediated immune system.

Zinc and vitamin A deficiency can occur together, with complex interactions between the compounds affecting liver metabolism of vitamin A. Zinc deficiency impairs vitamin A mobilization from the liver.

A zinc deficiency results in a decreased feed intake in all species and is probably the reason for the depression of growth rate in growing animals and body weight in mature animals. Failure of keratinization resulting in parakeratosis, loss and failure of growth of wool and hair, and lesions of the coronary bands probably reflects the importance of zinc in protein synthesis. There are lesions of the arteriolar walls of the dermis. The bones of zinc-deficient ruminants reveal abnormal mineralization and a reduction of zinc concentration in bones and cartilage and should be considered in animals with evidence of chondrodysplasia.4 Retarded testicular development occurs in ram lambs, and complete cessation of spermatogenesis suggests impairment of protein synthesis.

**CLINICAL FINDINGS**

**Pigs**
A reduced rate and efficiency of body weight gain is characteristic. Circumscribed areas of erythema appear in the skin on the ventral abdomen and inside the thigh. These areas develop into papules 3 to 5 mm in diameter, which are soon covered with scales, followed by thick crusts. These crusts are most visible in areas about the limb joints, ears, and hair and are distributed symmetrically in all cases. The crusts develop fissions and cracks, become quite thick (5 to 7 mm), and are easily detached from the skin. They are crumbly and not flaky or scaly. No greasiness is present except in the depths of fissures. Little scratching or rubbing occurs. Diarrhea of moderate degree is common. Secondary subcutaneous abscesses occur frequently, but in uncomplicated cases, the skin lesions disappear spontaneously in 10 to 45 days if the ration is corrected. Affected boars have testicular abnormalities that impair fertility.

**Ruminants**
In the naturally occurring disease in cattle, in severe cases, parakeratosis and alopecia may affect about 40% of the skin area. The lesions are most marked on the muzzle, vulva, anus, tailhead, ears, backs of the hind-legs, kneefolds, flank, and neck. Most animals have below-average body condition and are stunted in growth. After treatment with zinc, improvement is apparent in 1 week and complete in 3 weeks. Experimentally produced cases exhibit the following signs:

- Poor growth
- A stiff gait
- Swelling of the coronets, hocks, and knees
- Soft swelling containing fluid on the anterior aspect of the hind fetlocks
- Alopecia
- Wrinkling of the skin of the legs, scrotum, and neck and head, especially around the nostrils and cartilages
- Hemorrhages around the teeth
- Ulcers on the dental pad

The experimental disease in cattle is manifested by parakeratotic skin, mainly on the hindlimbs and udder, and similar lesions on teats, which tend to become eroded during milking. The fetlocks and pasterns are covered with scabby scales. There is exudation first with matting of hair, then drying and cracking. The skin becomes thickened and inelastic. Histologically, there is
parakeratosis. Clinical signs develop about 2 weeks after calves and lambs go onto a deficient diet so that there is no evidence of storage of zinc in tissues in these animals. In goats, hair growth, testicular size, and spermatogenesis are reduced, and growth rate is less than normal. Return to a normal diet does not necessarily reverse these signs, and the case-fatality rate is high. There is a marked delay in wound healing.

Zinc deficiency increases the risk of mastitis in dairy cows, potentially because of adverse alterations in mammary duct epithelium. Deficiency is associated with increased somatic-cell numbers in milk, decreased thickness of stratum corneum in ductus papillaris, and increased leukocyte infiltration of udder parenchyma.

Inherited zinc deficiency in cattle (lethal trait A46), which is caused in Holstein–Friesian cattle by a splice-site variant in SLC39A4, is described under the heading "Inherited Parakeratosis of Calves" later in this chapter. An inherited syndrome in Fleckvieh cattle with similar phenotype is not a result of zinc deficiency, and it does not have the same genetic abnormality.

Sheep

The natural disease in sheep is characterized by loss of wool and the development of thick, wrinkled skin. Wool-eating also occurs in sheep and may be one of the earliest signs noticed in lambs after being on a zinc-deficient diet for 4 weeks. Induced cases in lambs have exhibited reduced growth rate, salivation, swollen hocks, wrinkled skin, and open skin lesions around the hoof and eyes.

The experimental disease in goats is similar to that in lambs. One of the most striking effects of zinc deficiency in ram lambs is impaired testicular growth and complete cessation of spermatogenesis. Diets containing 2.44 to 17.4 mg/kg dry matter (DM) caused poor growth, spermatogenesis, and other signs of zinc deficiency. Diets containing 2.44 mg/kg DM caused poor growth, spermatogenesis, and other signs of zinc deficiency within 20 to 24 weeks. A diet containing 17.4 mg/kg DM of zinc is adequate for growth, but a content of 32.4 mg/kg DM is necessary for normal testicular development and spermatogenesis. On severely deficient experimental diets, other clinical signs in young rams are as follows:

- Drooling copious amounts of saliva when ruminating
- Parakeratosis around eyes and on nose, feet, and scrotum
- Shedding of the hooves
- Dystrophy and shedding of wool, which showed severe staining
- Development of a pungent odor

In naturally occurring cases in rams, the animals stood with their backs arched and feet close together.

A marginal zinc deficiency in ewes may be characterized by only a reduction in feed intake and a slightly reduced body weight, and no other external signs of disease. This is important because, in grazing ruminants, the lack of external signs indicates that zinc deficiency could easily pass undetected.

Infertility in Ewes

Infertility in ewes and a dietary deficiency of zinc have not been officially linked, but a zinc-responsive infertility has been described in ewes. Again, attention is drawn to the need for response trials when soil and pasture levels of an element are marginal.

An experimental zinc deficiency in pregnant ewes results in a decrease in the birth weight of the lambs and a reduced concentration of zinc in the tissues of the lambs; these effects are a result of the reduced feed intake characteristic of zinc deficiency. The zinc content of the diet did not significantly influence the ability of the ewes to become pregnant or maintain pregnancy. The combination of pregnancy and zinc deficiency in the ewe leads to highly efficient utilization of ingested zinc, and the developing fetus will accumulate about 35% of the total dietary intake of zinc of the ewe during the last trimester of pregnancy. The disease is correctable by the supplementary feeding of zinc.

Goats

Experimentally induced zinc deficiency in goats results in poor growth, low food intake, testicular hypoplasia, rough dull coat with loss of hair, and the accumulation of hard, dry, keratinized skin on the hindlimbs, scrotum, head, and neck. On the lower limbs the scabs fissure, crack, and produce some exudate. In naturally occurring cases in pygmy goats there was extensive alopecia, a kyphotic stance, extensive areas of parakeratosis, abnormal hoof growth, and flaky, painful coronary bands. A zinc-responsive alopecia and hyperkeratosis occurs in Angora goats. Affected animals had recurrent priuritis; hyperemia; exfoliation, fleece loss over the hindquarters, face, and ears; and a decline in reproductive performance. Zinc supplementation (40 or 80 mg/d) increases rate of fleece growth, plasma testosterone concentrations, and serum alkaline phosphatase activity in Cashmere goats.

Immediately before parturition in cows, there is a precipitate fall in plasma zinc concentration, which returns to normal slowly after calving. The depression of zinc levels is greater in cows that experience dystocia. This has led to the hypothesis that dystocia in beef heifers may be caused in some circumstances by a nutritional deficiency of zinc and that preparturient supplementation of the diet with zinc may reduce the occurrence of difficult births. This phenomenon does not appear to occur in sheep. The level of serum zinc increases in cattle during the season of facial eczema when sporidesmin intoxication causes depletion of liver zinc.

CLINICAL PATHOLOGY

Skin Scrapping

Laboratory examination of skin scrapings yields negative results, but skin biopsy will confirm the diagnosis of parakeratosis.

Zinc in Serum and Hair

Serum zinc levels may have good diagnostic value. Normal levels are 80 to 120 µg/dL (12.2 to 18.2 µmol/L) in sheep and cattle. Calves and lambs on deficient diets may have levels as low as 18 µg/dL (3.0 µmol/L). Dairy cattle with serum zinc less than 9.7 µmol/L are at increased risk of changes that predispose to mastitis.

Normal serum zinc levels in sheep are above 78 µg/dL (12 µmol/L), and values below 39 µg/dL (6 µmol/L) or less are considered as evidence of deficiency. There is a general relationship between the zinc content of the hair and the level of zinc in the diet, but the analysis of hair is not considered to be a sufficiently accurate indicator of an animal’s zinc status. In experimental disease in piglets, there is a reduction in serum levels of zinc, calcium, and alkaline phosphatase, and it is suggested that the disease could be detected by measuring the serum alkaline phosphate and serum zinc levels. Levels of zinc in the blood are very labile, and simple estimations of levels alone are likely to be misleading. For example, other intercurrent diseases commonly depress serum calcium and copper levels. In addition, zinc levels in plasma fall precipitately at parturition in cows; they are also depressed by hyperthermal stress. After 1 week on a highly deficient diet, serum zinc levels fall to about 50% of normal, or pretreatment, levels.

NECROPSY FINDINGS

Necropsy examinations are not usually performed, but histologic examination of skin biopsy sections reveals a marked increase in thickness of all the elements of the epidermis. Tissue levels of zinc differ between deficient and normal animals, but the differences are statistical rather than diagnostic.

DIFFERENTIAL DIAGNOSIS

Sarcoptic mange may resemble parakeratosis, but is accompanied by much itching and rubbing. The parasites may be found in skin scrapings. Treatment with appropriate parasiticides relieves the condition. Exudative epidermitis is quite similar in appearance, but occurs chiefly in unweaned pigs. The lesions have a greasy character that is quite different from the dry, crumbly lesions of parakeratosis. The mortality rate is higher.

TREATMENT

In outbreaks of parakeratosis in swine, zinc should be added to diet immediately at the rate of 50 mg/kg DM (200 mg of zinc sulfate or carbonate per kg of feed). The calcium...
level of the diet should be maintained at between 0.65% and 0.75%. The injection of zinc at a rate of 2 to 4 mg/kg BW daily for 10 days is also effective.

Zinc oxide suspended in olive oil and given IM at a dose of 200 mg of zinc for adult sheep and 50 mg of zinc for lambs will result in a clinical cure within 2 months. The oral administration of zinc at the rate of 250 mg zinc sulfate daily for 4 weeks resulted in a clinical cure of zinc deficiency in goats in 12 to 14 weeks.

**CONTROL**

**Pigs**
The calcium content of diets for growing pigs should be restricted to 0.5% to 0.6%. However, rations containing as little as 0.5% calcium and with normal zinc content (30 mg/kg DM) may produce the disease. Supplementation with zinc (to 50 mg/kg DM) as sulfate or carbonate has been found to be highly effective as a preventive, and there appears to be a wide margin of safety in its use, with diets containing 1000 mg/kg DM added zinc having no apparent toxic effect. Organic and inorganic zinc supplements are handled differently by pigs, with organic forms of zinc being more bioavailable. Rapidly growing pigs require 75 mg/kg of organic zinc in a complex nursery diet to maximize growth, health, and well-being. The standard recommendation is to add 200 g of zinc carbonate or sulfate to each ton of feed. Weight gains in affected groups are appreciably increased by the addition of zinc to the diet. The addition of oils containing unsaturated fatty acids is also an effective preventive. Access to green pasture, reduction in feed intake, and the deletion of growth stimulants from rations will lessen the incidence of the disease but are not usually practicable.

**Ruminants**

For cattle, the feeding of zinc sulfate (2 to 4 g daily) is recommended as an emergency measure followed by the application of a zinc-containing fertilizer. As an alternative to dietary supplementation for ruminants, an intraruminal pellet has been demonstrated in sheep. It was effective for 7 weeks only and would not be satisfactory for long-term use. The creation of subcutaneous depots of zinc by the injection of zinc oxide or zinc metal dust has been demonstrated. The zinc dust offered a greater delayed effect. A soluble glass bolus containing zinc, cobalt, and selenium was able to correct experimentally induced zinc deficiency in sheep. The bolus supplied the daily requirement of the sheep for zinc with no detrimental effect on their copper status, although high-dose zinc supplementation does impair copper absorption in cattle that are provided additional copper in the diet.

Zinc-methionine, an organic zinc supplement for dairy goats, improved udder health, an enhanced the absorption of nitrogen, and increased nitrogen retention. Recommended dietary intake of zinc for Cashmere goats is 86 mg/kg DM during the breeding season and cashmere-fiber growing period.

**PLANT POISONING ASSOCIATED WITH KNOWN TOXINS**

**DIANTHRONE DERIVATIVES**

Hypericin, a complex derivative of dianthrone, is found in *Hypericum perforatum* (St. John’s wort or Klamath weed) and *Hypericum triquetrifolium* and is the prototypical primary photosensitizing agent. All parts of these plants are associated with photosensitive dermatitis when ingested by sheep and cattle, but they have to be eaten in large quantities. They are not very palatable, and outbreaks occur when they are in the young stage and dominate the pasture. Narrow-leaf varieties contain 2 or 3 times as much hypericin as broadleaf varieties, and the flowering tops are 6 to 9 times as toxic as the foliage. Clinical signs may appear within a few days of livestock going onto affected fields and usually disappear within 1 to 2 weeks after removal from them. Experimental production of poisoning with *H. perforatum* has shown that the plant contains a primary photodynamic agent. There is neither liver damage nor loss of hepatic function.

**FAGOPYRIN**

Fagopyrin, a red helianthrone pigment found in *Fagopyrum sagittatum* (buckwheat), is associated with primary photosensitization in all species.

**FUROCOUMARIN**

Plants containing furocoumarins (including psoralsens) include the following:
- *Ammi majus*—bishop’s weed, meadow sweet
- *Ammi visnaga*—visnaga
- *Cooperia pedunculata*—thunder lily
- *Cymopterus longipes*—thunder lily
- *Cymopterus watsonii*—wild or spring parsley
- *Heracleum mantegazzianum*—giant hogweed
- *Petroselinum spp.*—parsley
- *Thamnosma texana*—Dutchman’s breeches, bluster weed

Similar furocoumarins, identified as 4,5,8-trimethylpsoralen, 5-methoxypsoralen, and 8-methoxypsoralen, are also present in *Pastinaca sativa* (parsnip root) infested with the fungus *Ceratocephalus fimbriatus*, and *Apium graveolens* (celery) infested with *Sclerotinia* spp. (pink-rot fungus). These toxins have the particular characteristic of being photosensitizing by contact, without the need for ingestion, and are associated with serious lesions in humans. *A. majus* is most poisonous to livestock when there are ripe seeds in the seedheads. Its most serious occurrence is as a contaminant in hay. *C. pedunculata*, a perennial forb of western range country in the United States, occurs at times of high humidity or after rain has wet the foliage, and the live as well as dead leaves are toxic.

The clinical syndrome associated with plants containing furocoumarins is one of photosensitizing dermatitis. It includes severe cutaneous dermatitis, sometimes as severe as cutaneous gangrene, on the white parts of the skin on the dorsal and lateral sides of the body and edema of the head and ears, the lateral aspects of the teats, the unpigmented conjunctiva, the muzzle and the oral mucosa inside the lower lip, and the undersurface of the tip of the tongue. Photosensitive dermatitis in pigs may be associated with distinctive vesicles on the snout and raise a false alarm of viral vesicular disease. One serious international incident arose out of a feeding of moldyparsnips.

**PLANT POISONINGS ASSOCIATED WITH UNIDENTIFIED TOXINS**

**DERMATITIS**

- *Entandrophragma cylindricum*—redwood; shavings as bedding associated with balanoposthitis in rams
- *Excoecaria* spp.
- *Heracleum mantegazzianum*—cow parsnip
- *Vicia benghalensis*—popany vetch; associated with dermatitis, conjunctivitis, rhinitis, fever, and multiple eosinophilic granulomas in many organs
- *Vicia dasycarpa*—woolly pod vetch; same symptoms as *V. benghalensis*
- *Vicia villosa*—hairy vetch; same signs as *V. benghalensis*

**PHOTOSENSITIZATION—PRIMARY; WITHOUT HEPATIC LESIONS**

- *Echinocloa utilis*—Japanese millet
- *Erodium cicutarium*—storksbill
- *Froelichia humboldtiana*<sup>2</sup>
- *Holocaryx glaziovii*
- *Lachnanthes tinctoria*
- *Mentha satureioides*
- *Sphenosicyon capitellatum*
- *Medicago polymorpha*—burr trefoil
- *Verbena* spp.
Photodermatitis associated with *M. polymorpha* and *F. humboldtiana* occurs in all animal species on pasture dominated by the plant, usually in the spring. Lesions on the unpigmented parts of the skin disappear quickly when animals are taken off the pasture; there is no liver damage or permanent after-effects. Aphids, which commonly infest the plant in very large numbers, contain large amounts of a photodynamic agent and may be important in some outbreaks of the disease.

**SELENIUM TOXICOSIS**

**SYNOPSIS**

Etiology Ingestion of plants or feed supplements or injection of pharmaceutical agents with excessive amounts of selenium.

Epidemiology Enzootic disease where soils and pasture contain toxic amounts of selenium; outbreaks after errors in feed supplementation or oral or injection doses.

Clinical pathology: Elevated concentration of selenium in body tissues and fluids.

Lesions:

Living Animals:

Acute: dyspnea, diarrhea, prostration, short course, death.

Chronic: emaciation, rough coat, stiff gait, lameness, hoof deformity.

Postmortem:

Acute: evidence of cardiovascular compromise, hemorrhages.

Chronic: skeletal and cardiac myopathies.

Diagnostic confirmation: Elevated selenium levels in body fluids and tissues.

Treatment: None; avoid pastures with selenium-containing plants; take care with medication and feed additives containing selenium.

**ETIOLOGY**

Selenium toxicity in animals is a worldwide problem, either as an acute or chronic poisoning. It is associated with the ingestion or injection of organic or inorganic selenium compounds as follows:

- Inorganic selenium compounds administered as feed supplements
- Organic selenocompounds (selenomethionine and methylselenocysteine) occurring in pasture plants
- Pharmaceutical preparations administered orally or by injection, frequently combined with vitamin E

Discrepancies exist in the toxic doses quoted in the literature, and the reasons for this are not fully understood. Identified animal factors include species, age, health, reproductive status, and nutritional status.

Other factors include dose, route of administration, and interactions with other dietary substrates. The daily intake of a diet containing 2 mg/kg BW of selenium can be marginally toxic for sheep, yet pregnant and lactating ewes tolerated doses as high as 12 mg dietary selenium (as sodium selenite) per kilogram of BW for 72 weeks without developing any clinical or pathologic signs of selenium toxicity. Oral ingestion of 1 to 2.2 mg of Se/kg BW as sodium selenite caused mortality in lambs, but other lambs have survived doses of 4 mg/kg BW. Feed containing 44 mg/kg selenium for horses and 11 mg/kg for pigs is associated with poisoning. Toxic single acute oral doses (as mg/kg BW) are 2.2 for sheep, 1.49 for horses, 9 for cattle, and 15 for pigs.

**EPIDEMIOLOGY**

**Occurrence**

Pastoral Selenium poisoning occurs in restricted areas in North America, Ireland, Israel, Canada, Australia, and South Africa where the soils are derived from particular rock formations containing a high content of selenium. The high level in these plants occurs from the high levels of selenium found naturally in the environment.

High levels of selenium in plants can also be found in areas where the soil is not naturally high in selenium. This is associated with industrial or commercial release of selenium into the water and soil.

**Dosing Errors**

Substantial losses as a result of selenium poisoning also occur because of misunderstanding about the dose rates of selenium compounds used therapeutically or prophylactically.

**Risk Factors**

**Animal Risk Factors**

Cattle are more tolerant than sheep. Pigs are unlikely to be exposed but can develop the disease in the field. Young animals are less tolerant than adults.

Dietary supplementation is used in the prevention of known deficiency syndromes such as white muscle disease in lambs, a nonspecific growth stimulant, and as a prophylactic for a large number of other vage syndromes. The concurrent administration of monensin and selenium increases the toxicity of the selenium being fed. There are many case reports of unexpected illness and mortality in animals dosed with selenium preparations, and it is apparent that not all of the factors affecting selenium toxicity are known.

Organic selenium compounds, especially those occurring naturally in plants, may be more toxic than inorganic compounds, but this difference may not be apparent in ruminants because of alterations in ingested compounds produced by digestive processes in the rumen. Selenium is more toxic than selenate, and both are more damaging than selenium dioxide.

**Environmental Risk Factors**

Industrial deposition (e.g., fly ash from coal power plants) has been shown to be associated with increased selenium levels in tissues from sheep grazing there.

**Farm Risk Factors**

Selenium poisoning in animals grazing plants growing on seleniferous soils may be restricted to very distinct areas as small as individual fields. A low rainfall predisposes to selenium poisoning because soluble, available selenium compounds are not leached out of the topsoil, and lack of competing forage may force animals to eat large quantities of selenium-containing plants.

The effective selenium is contained in the top 60 to 90 cm of the soil profile, selenium at lower levels than this not being within reach of most plants. Selenium poisoning may occur on soils containing as little selenium as 0.01 mg/kg, but some soils may contain as much as 1200 mg/kg. Most pasture plants seldom contain selenium in excess of 100 ppm, but a number of species, the so-called converter or indicator plants, take up the element in such large quantities that selenium levels may reach as high as 10,000 ppm. Included in this category are *Acacia cana*; *Artemisia canescens*; *Aster* spp.; some of the *Astragalus*, *Atriplex*, and *Castilleja* spp.; *Comandra pallida*; *Descurainia pinnata*; *Griselidia* spp.; *Machaeranthera ramosa*; *Morinda reticulata*; *Neptunia amplexicaulis*; *Onopsis*, *Penstemon*, and *Sideranthus* spp.; *Stanleya pinnata*; and *Xylorhiza* spp.

These plants tend to grow preferentially on selenium-rich soils and are thus “indicator” plants. They are in general unpalatable because of a strong odor, and thus an acute syndrome is unlikely, but heavy losses have been attributed in the past to a chronic form of the disease known as alkali disease.

**PATHOGENESIS**

Ingested selenium compounds are absorbed primarily in the duodenum, with some absorption in the remainder of the small intestine. Little, if any, absorption occurs in the rumen. The mechanism of absorption varies depending on the specific form of selenium, with selenite absorption by passive transfer and selenomethionine and selenocysteine by active transport. Tissue distribution also depends on the form of selenium, with the kidney and liver ultimately having the highest concentration of selenium. Placental transfer occurs, especially in the last trimester; little is excreted in the milk. Metabolism occurs in the red blood cells and liver; excretion is primarily through urine, with a small amount of
metabolized selenium excreted in the bile and feces. The mechanism of action is not well understood, and several different theories have been proposed. Selenium occurs in plants in analogs of the sulfur-containing amino acids (e.g., selenocysteine), and a possible mechanism of intoxication is by interference with enzyme systems that contain these amino acids. Other proposed mechanisms include generation of free radicals, causing oxidative tissue damage, and incorporation into proteins, causing disruption of normal cell function.

**CLINICAL FINDINGS**

**Acute Poisoning**

In naturally occurring and experimental poisoning there is severe respiratory distress, restlessness, complete anorexia, salivation, watery diarrhea, fever, tachycardia, abnor-

**Chronic Poisoning**

Chronic poisoning is manifested by dullness, emaciation, rough coat, lack of vitality, stiff-

**CLINICAL PATHOLOGY**

A moderate anemia occurs in acute and chronic poisoning, and a depression of hemoglobin levels to about 7 g/dL is one of the early indications of selenium poisoning. Selenium can be detected in the urine, milk, and hair of affected animals. Clinical illness is evident at blood levels of 3 mg/kg and at urine levels of more than 4 mg/kg of selenium. Normal serum levels of 140 to 190 ng/mL are elevated to the level of 1500 ng/mL.

Critical levels of selenium in hair include the following:
- Less than 5.0 mg/kg suggests that chronic selenium is unlikely.
- From 5.0 to 10.0 mg/kg suggests borderline problems.
- More than 10 mg/kg is diagnostic of chronic selenium.

**NECROPSY FINDINGS**

**Acute**

In confirmed cases of natural or experimentally produced acute selenium poisoning, most of the macroscopic findings can be attributed to cardiovascular compromise. There is pulmonary edema and congestion, petechiation of the thoracic viscera, and congestion of the liver, kidneys, and gastrointestinal tract. In parenterally overdosed lambs and piglets there is usually hydrothoe-

**Chronic**

In animals suffering from subacute to chronic selenium poisoning there is a skeletal and cardiac myopathy. Deformities of the feet and skin are usually apparent. Atrophy and dilatation of the heart and pulmonary edema, cirrhosis and atrophy of the liver, glo-

**Selenium Levels in Tissue**

In chronic selenium poisoning there is a skeletal and necrosis of hepatocytes. Cardiac myocytes may appear swollen and contain areas of cytoplasmic granularity and lysis.

**DEFERENTIAL DIAGNOSIS**

**TREATMENT**

A number of substances have been tried in the treatment of selenium poisoning, including potassium iodide, ascorbic acid, and beet pectin, but without apparent effect. The use of BAL is contraindicated.

**CONTROL**

Selenium in feeds should not exceed 5 mg/kg dry matter if danger is to be avoided, and feeding on pasture containing 25 mg/kg dry matter for several weeks can be expected to be associated with chronic selenium poisoning. Pasture may contain as much as 2000 to 6000 mg/kg of selenium and is associated with the acute form of the disease when fed for a few days.

Protection against the toxic effects of selenium in amounts up to 10 mg/kg in the diet has been obtained by the inclusion in the ration fed to pigs of 0.01% to 0.02% of arsanilic acid or 0.005% of 3-nitro-4-hydroxy-phenyl arsanic acid. In cattle, 0.01% arsanilic acid in the ration or 550 mg/day to grazing steers gives only slight protection. The addition of linseed oil to the ration improves the efficiency of this protection. A high-protein diet also has a general protective effect.

When using selenium as a pharmaceutical agent, strict attention should be paid to the recommended dose and route of administration.

IODINE TOXICOSIS

ETIOLOGY

Iodine is found in low concentrations in nature both as inorganic and organic forms. Common sources of iodine include iodized salt (100 ppm iodine), ethylenediamine dihydroiodide (EDDI), and iodine containing feed additives such as calcium iodate, potassium iodide, and sodium iodide.1 Potassium iodide, the most water-soluble and chemically unstable form, is the least commonly used product in cattle feed; calcium iodate is the most stable product. Ethylenediamine dihydroiodide is often used to prevent or treat footrot in cattle but has never been used in other countries to treat pythiosis in horses.

Poisoning with inorganic iodine products is rarely associated with illness in animals. Excretion in milk and eggs is linear, and the toxic dose is large. As the amount of inorganic iodine ingested increases, so does the amount excreted in milk, with a fairly constant excretion ratio of 8% to 12% iodine.2 Doses of 10 mg/kg BW daily are usually required to produce fatal illness in calves. There is a special occurrence of goiter in foals when the foal and the dam are fed excessive amounts of iodine, especially when kelp is fed as a dietary supplement. Intakes of 35 to 40 mg iodine/day in a mare can be associated with the development of goiter in her foal.

Toxicity with organic iodides has also occurred at much lower levels of intake (e.g., 160 mg/day per cow) and appears to be a practical risk when cows or calves are fed EDDI constantly as a prophylactic against footrot.

CLINICAL FINDINGS

Clinical signs vary depending on the species and form of iodine. Horses appear to be the most sensitive to iodine toxicosis, followed by ruminants and then pigs.2 In cattle and sheep, signs include heavy dusting of the hair coat with large-sized dandruff scales, hair loss, dryness of the coat, coughing, and profuse nasal discharge.3 Feed intake and milk production are often decreased. Other common signs in ruminants include lacrimation, hyperthermia, and hypersalivation. Exophthalmos occurs in some cases, and severely affected animals may die of bronchopneumonia. In horses, alopecia and heavy dandruff are characteristic. Anhidrosis, rhabdomyolysis, and exercise intolerance have also been reported.2

CLINICAL PATHOLOGY/NECROPSY

Serum iodine levels are elevated above the normal level of 5 μg/100 mL up to 20 to 130 μg/mL.

Most of the postmortem lesions are associated with changes in the respiratory tract, with tracheitis, bronchopneumonia, and pleurisy reported in cattle. Lung tissue shows exudative inflammation, hypertrophy of the bronchial mucous membranes, bronchole necrosis, and fibrinous exudate in the alveoli. Sheep with iodine toxicosis showed suppurative bronchopneumonia and fibrinous pneumonia.

SQUAMOUS-CELL CARCINOMA

Squamous-cell carcinoma can occur anywhere on the skin, and also in the mouth and maxillary sinus. Squamous-cell carcinoma in cattle and horses may develop as an uncommon complication of an infection with bovine papillomavirus type 1 and 2.1 Common types are as follows:

• **Ocular squamous-cell carcinoma** (cancer—eye) is the commonest lesion, on the eyelids and the eyeball in horses and cattle (see also “Bovine Ocular Squamous-Cell Carcinoma” and “Equine Ocular Squamous-Cell Carcinoma”)

• **Squamous-cell carcinomas in horses** are the second most common cutaneous neoplasia (after the equine sarcoid) in this species and primarily affect the glans penis and prepuce and the paravulvar region of aged horses.2 Squamous-cell carcinoma can cause fatal metastases unless the primary tumor is resected in the early stages. Grossly similar lesions are caused by epithelial hyperplasia, habronemiasis, and squamous papillomata.

• **Vulvar squamous-cell carcinoma** appears frequently in Merino ewes as a result of excessive exposure of vulvar skin to sunlight after radical perineal surgery to help control blow-fly strike. Squamous-cell carcinomas also occur on the vulva of cattle, and a greater incidence has been observed on unpigmented than on pigmented vulvas.

• **Horn cancer** in cattle and rarely in sheep, goats, and buffaloes is a squamous-cell carcinoma arising from the pseudostratified columnar epithelium of the horn core mucosa; it is most prevalent in *Bos indicus* breeds. This tumor affects approximately 1% of the Indian cattle population and accounts for over 80% of reported tumors in Indian cattle. Steers have been reported to be affected more frequently than female animals. In the early stages, affected animals may rub the horns against a fixed object or shake the head frequently. A bloody discharge begins from the nostril on the affected side, or from the base of the horn, and the animal holds its head down and toward one side. The horn becomes loosened and falls off, leaving the tumor exposed to infection and fly infestation. Secondary metastases are common. The high prevalence of metastases in regional lymph nodes and internal organs discourages treatment, but a phenol extract of horn core tissue is immunogenic, and immunotherapy may be a successful treatment technique. Other forms of therapy are also practiced for squamous-cell carcinoma generally, including surgical excision.
preferably by cryotherapy, and radiofrequency hyperthermia.

- **Ear cancer** in sheep is in most cases a squamous-cell carcinoma. The lesion commences around the free edge of the ear and then invades the entire ear, which becomes a large, cauliflower-shaped mass. A high incidence may occur in some flocks, but the cause is not known; the presence of papillomavirus in many aural precancerous lesions suggests that the virus may participate in the etiology.

- **Ovine skin cancer:** A high incidence of epitheliomas has been recorded in some families of merino sheep in Australia. The lesions occur on the woollen skin and are accompanied by many cutaneous cysts. It has been suggested that predisposition to the neoplasm is inherited. Metastasis is common with both epitheliomas and squamous-cell carcinomas.

- **Brand cancer,** which occurs as a granulomatous mass at the site of a skin fire or freeze brand, is usually considered to be of chronic inflammatory rather than neoplastic origin, but squamous-cell carcinomas are recorded at branding sites in sheep and cattle.

- **In goats,** the perineum is a common site for squamous-cell carcinoma. The udder, ears, and base of the horns may also be affected. Ulceration, flystrike, and matting of hair are unattractive swellings. A bilaterally symmetric vulvar swelling as a result of ectopic mammary tissue that enlarges at parturition is likely to be confused with squamous-cell carcinoma. Milk can be aspirated from the swellings.

**REFERENCES**

**MELANOMA**

Melanomas are skin neoplasias commonly occurring in pigs, horses, cattle, small ruminants, and camels. In horses, between 4% and 15% and in cattle approximately 6% of all tumors were reported to be melanomas. In horses, melanomas primarily occur in mature gray- and white-coated horses, reaching a prevalence of over 80% in this subgroup of animals. Although historically melanomas were considered to be benign skin proliferations, more recently the concept of melanoma as a neoplasm with malignant potential has become more accepted. Some sources claim that at least 66% of melanocytic tumors in horses eventually become malignant.

Four types of melanocytic abnormalities are recognized in horses: melanomas are the perineum, tail base, sheath, commissures of the lips, jugular furrow, and subauricular lymph nodes. Although in many cases tumors may exist for many years without causing any clinical signs, the skin may ulcerate in rapidly growing tumors, leading to secondary bacterial infection. Large masses in the perianal region may impair defecation and result in fecal impaction. Similarly, large tumors in the neck area may impair head movement and the ability to eat, drink, and swallow. Visceral metastatic masses may occur in more advanced cases.

**CLINICAL PATHOLOGY**

Although the location, appearance, and color of a mass can be highly suggestive, an excisional biopsy, which involves surgically removing small tumors integrally and submitting them to a diagnostic laboratory for histologic confirmation of the diagnosis, has been recommended whenever possible.

**TREATMENT**

Single noninvasive tumors of small to moderate size have been surgically excised with good success and good prognosis. Surgical excision is unrewarding in cases with multiple tumors, infiltrating masses, or masses located around the parotid salivary gland, which complicate the surgical approach considerably.

In horses, treatment with oral cimetidine, a histamine type 2 receptor antagonist, either at a dose of 2.5 mg/kg BW q8h or 7.5 mg/kg BW q24h p.o., for at least 60 days has yielded variable results. Promising results were reported with the use of cisplatin, either as repeated intratumoral injection or as biodegradable beads in horses.

**REFERENCES**

**LIPOMA**

Lipomas are benign subcutaneous or submucosal tumors that can be locally extensive and consist of well-differentiated adipocytes. Lipomas are occasionally seen in horses but are rare in cattle. In horses, lipomas occur either as mesenteric or cutaneous lipomas. Mesenteric lipomas predominantly develop in older horses, presenting as pedunculated lipomas that may cause secondary complications such as intestinal strangulation.

**REFERENCES**

Subcutaneous lipomas are the predominant form in young horses less than 2 years of age. The large majority of cutaneous lipomas are encapsulated and well demarcated from surrounding tissue, making them easily resectable, with minimal risk for recurrence. Occasionally lipomas may grow invasively, infiltrating surrounding tissue such as muscles, tendons, joints, and even bone. Despite their invasive growth, infiltrative lipomas are benign because they do not metastasize. The invasive growth pattern makes integral resection of tumorous tissue impossible and results in high recurrence rates after surgical intervention. Differentiating between lipomas and infiltrative lipomas is important to determine the eligibility for surgical resection and the prognosis but can be challenging under field conditions.

In foals and calves, congenital external infiltrating lipomas have been reported.

**REFERENCES**

**MAST CELL TUMORS**

A mast cell tumor (mastocytoma) is a rare neoplasia primarily affecting the skin in cattle, horses, swine, and New World camelids. The large majority of mast cell tumors in cattle and horses are benign, but malignant forms have been described. Less than 6% of all equine and less than 1% of all bovine neoplasias have been identified as mastocytomas. Incidental case of mast cell tumors have been reported in pigs, small ruminants, and New World camels. Mast cell tumors in the species just mentioned are most frequently located in the skin, with no apparent site of predilection. Other than on the skin, mastocytomas in horses have also been identified in the gastrointestinal tract, salivary glands, eyes, testes, and spleen. In cattle, apart from the cutaneous form, mast cell tumors have been found in spleen, lung, liver, lymph nodes, muscle tissue, omentum, abomasum, tongue, and uterus.

**CLINICAL FINDINGS**

Animals of all ages can be affected, and neither a gender nor a breed predilection has been reported. Single lesions are the most common presentation, but cases of multicentric mastocytoma have been reported in different species. In most instances a mastocytoma presents as slow-growing, indolent cutaneous or subcutaneous mass. Lesions typically are well demarcated and vary from 0.5 to 20 cm in diameter and feel firm or fluctuating on palpation. Masses located on the limbs are often firm and immovable. The overlying skin is usually intact, although alopecia, hyperpigmentation, or ulceration may be present.

**CLINICAL PATHOLOGY**

Diagnosis of cutaneous mastocytoma is either by fine-needle aspiration or excisional biopsy, removing the mass integrally. Histo logically mast cell tumors are characterized by the predominance of well-differentiated mast cells. Mitotic figures are few in number, and eosinophilic infiltration of the mass is a consistent finding. Older lesions may contain considerable amount of fibrosis, mineralization, and necrosis.

**TREATMENT**

Cutaneous mastocytomas in cattle and horses in general are benign and indolent, but they rarely resolve spontaneously. Surgical excision may therefore be indicated for cosmetic reasons or when masses cause discomfort, and surgery is usually curative. Other reported treatments include cryosurgery and the intra- or sublesional injection of corticosteroids (e.g., 10 to 20 mg methylprednisolone acetate).

**REFERENCES**

**LYMPHOMATOSIS**

In cattle and horses, skin lesions occur as nodules in the subcutaneous tissue, most commonly in the paralumbar fossae and the perineum. In cattle, the lesions are associated with the virus of enzootic bovine leukosis (EBL) and are only one manifestation of the disease, usually being accompanied by lesions in other organs. In horses, there are no leukemic lesions in lymph nodes or visceral organs.

**NEUROFIBROMATOSIS**

This common lesion of nerves in cattle usually attracts attention only in abattoir specimens but can occur in a cutaneous form resembling a similar disease of humans; a particularly high prevalence of this benign disease is recorded in breeds of European cows. In cattle, clinical cases are usually recorded in calves, in which there are cutaneous lesions that appear as tumor-like lumps between the eyes and on the cheeks. They are flat, round tumors up to 8 cm in diameter and of a lumpy, elastic consistency.

**HISTIOCYTOMA**

Histiocytomas originate from epidermal Langerhans cells of antigen-presenting lineage. This is a very rare benign neoplasm in farm animals but is recorded as cutaneous nodules or plaques, which bleed easily, in goats and cattle. The lesions regress spontaneously.

**CUTANEOUS ANGIOMATOSIS**

Angiomatosis is vasoproliferation originating from endothelial cells from blood vessels. The etiology of this condition that is rarely observed in horses, cattle, swine, small ruminants, and New World camels is not yet understood. Causes discussed in the literature are inflammatory reactions, bacterial or viral infection, congenital abnormalities, and hyper- or neoplastic transformations.

In cattle, cutaneous angiomatosis most commonly presents as single or multiple cutaneous lesions situated most commonly along the dorsum of the neck characterized by recurrent profuse hemorrhage. The lesions consist of what appears to be protruding granulation tissue and are benign. Histo logically angiosmas are characterized by the nonencapsulated proliferation of vascular tissue that may or may not be infiltrated with inflammatory cells.

A juvenile version of angiomatosis in calves is characterized by similar lesions but in many organs, sometimes including the skin.

Surgical excision is effective.

**HEMANGIOMA AND HEMANGIOSARCOMA**

Benign vascular proliferations are occasionally encountered in most animal species. Cutaneous hemangiomas of young horses are morphologically the same as bovine cutaneous angiomatosis lesions. Young horses usually present with solitary lesions between 1 and up to 30 cm in diameter on distal parts of the limbs. The lesions can consist of nodules or plaques with firm to fluctuating consistency that bleed easily. The skin overlying the proliferation tends to be dark colored, hyperkeratotic, and associated with local alopecia.

Hemangiosarcomas (hemangioepithelioma) are malignant tumors recorded relatively frequently in older horses. They are large, highly vascular, subcutaneous masses, usually associated with one or more internal lesions. The primary lesion may be internal, commonly in the spleen, or cutaneous. Recurrence after excision, extensive local infiltration, and death as a result of anemia are common sequelae.

**CONGENITAL SKIN TUMORS**

Congenital tumors are defined as those existing at birth. A broader definition is that congenital tumors can be detected in fetuses and in newborns until 2 months of age. Embryonic tumors are those that arise during embryonic, fetal, or early postnatal development from a particular organ rudiment or tissue while it is still immature. Hamartomas are benign, tumor-like nodules composed of
overgrowth of mature cells, which normally occur in the affected part but often with one element predominating. Hamartomas include hemangiomas, ameloblastomas, and rhabdomyomas. Teratomas are true neoplasms consisting of different types of tissue not native to the area in which they occur.

**Cattle**
Congenital skin neoplasms of cattle described include mast cell tumors, lymphosarcoma, myxoma, and vascular hamartoma. Benign melanomas, mastocytomas, hemangiomas and lymphangiomatas, fibrosarcomas, neurofibromatosis, subcutaneous lipomas, multiple lipomas, and retroperitoneal lipomas have also been recorded in calves. The comparative aspects of tumors in calves have been described.

**Pigs**
The literature on congenital and hereditary tumors in piglets has been reviewed. Spindle-cell sarcoma, malignant melanoma, and papillomatosis are common congenital tumors of the skin of piglets. Congenital cutaneous papillomatosis of the head and neck of a newborn piglet has been described on a pig-breeding farm where sporadic cutaneous papillomatosis of the prepuce and scrotum had previously occurred in several boars.

**Foals**
Congenital tumors in foals are rare. Congenital skin tumors are of the papillomatous, vascular, and melanocytic types. The vascular tumors are capillary hemangiomas, cavernous hemangiomas, and hemangiosarcomas.

**FURTHER READING**

**INHERITED ALBINISM**
Albinism is a congenital lack of melanin pigment in the skin, hair, and other normally pigmented structures such as the uveal tract. Albinism is classified as generalized or localized and as complete, partial, or incomplete. The affected skin in albinism is characterized microscopically as melanopenic rather than melanocytopenic, which distinguishes partial albinism from piebaldism. Most of the normal, inherited white markings that occur on horses are localized forms of piebaldism. Generalized and complete albino animals (oculocutaneous albinism) have white hair, white skin, and pink irides, and they usually exhibit photophobia. Generalized albinism in the horse is inherited as an autosomal-dominant trait that is only viable in the heterozygous states. These horses have incomplete albinism because there is some coloration to the iris.

**DISORDERS OF COAT COLOR, PSEUDOALBINISM, AND LETHAL WHITES**
There are a number of forms of pseudoalbinism and disorders of coat color in domestic animals that involve congenital systemic production. Skin is fragile and hyperextensible from birth on, with disturbed wound healing.

- **Nevis** is an irregularly shaped, cutaneous defect, present at birth and originally covered with hair, but subsequently hairless. Depending on which cells are involved, a nevis is referred to as vascular, epidermal, connective tissue, or melanotic nevus. Individual lesions are 3 to 4 cm in diameter, bright pink, ulcerated, and inflamed. Vascular nevi consist of densely packed convoluted blood vessels, which bleed easily. Most lesions are on the lower limbs, especially at the coronet.

- **Dermoid cysts** are cystic structures occasionally observed in horses and other species containing hair, exfoliated skin, and glandular debris. Dermoid cysts are present at birth but may become apparent later in life as they grow in size.

- **Inherited epidermal dysplasia (bald calf syndrome)** of Holstein–Friesian calves is an autosomal-recessive inherited lethal condition. Calves appear normal at birth but progressively lose hair and condition; they have elongated and narrow hooves and scaly skin. Secondary skin ulceration and failure of horn development occur.

REFERENCES
INHERITED SYMmetric ALOPECIA

Inherited symmetric alopecia is an inherited skin defect of cattle in which animals born with a normal hair coat lose hair from areas distributed symmetrically over the body. It has been observed in Holstein cattle as a rare disease, but its appearance among valuable purebred cattle has economic importance. It appears to be inherited as a single autosomal-recessive character. Loss of hair commences at 6 weeks to 6 months of age. The alopecia is symmetric and commences on the head, neck, back, and hindquarters, and progresses to the root of the tail, down the legs, and over the forelimbs. Affected skin areas become completely bald. Pigmented and unpigmented skin is equally affected; there is no irritation, and the animals are normal in other respects. Failure of hair fibers to develop in apparently normal follicles can be detected by skin biopsy.

INHERITED CONGENITAL HYPOTRICHOSIS

In inherited congenital hypotrichosis there is partial or complete absence of the hair coat with or without other defects of development. The main importance of the disease is in cattle, in which there are six syndromes, but it is also inherited in pigs, in which it is associated with low birth weight, weakness, and high mortality, and in Poll Dorset sheep, in which the face, ears, and lower legs are bald; there are no eyelashes; and the patient lacrimates excessively. The skin is thick, wrinkled, greasy, scaly, and erythematous. Hair fibers are completely absent from the follicles, but wool fibers and follicles are normal.

Viable Hypotrichosis
Viable hypotrichosis is recorded in North America in Guernsey and Jersey cattle. Calves are viable provided they are sheltered. They grow normally but are unable to withstand exposure to cold weather or hot sun. In most instances hair may be present in varying amounts at birth but is lost soon afterward. There is no defect of horn or hoof growth. The skin is normal but has a shiny, tanned appearance and on sections no hair follicles are present in the skin. The condition is inherited as a single recessive character. Congenital hypotrichosis has been reported in a Percheron draught horse. At birth there were circumscribed patchy areas of alopecia that was progressive, becoming almost complete by 1 year of age. Skin biopsy at 7 months of age revealed severe follicular hypoplasia, and the animal was still alive at 6 years of age.

Nonviable Hypotrichosis
Nonviable hypotrichosis is a complete hypotrichosis in which the thyroid is abnormally small and hypofunctional and the calves die shortly after birth.

CONGENITAL HYPOTRICHOSIS AND ANODONTIA (ANHIDROTIC ECTODERMAL DYSPLASIA)

Congenital X-linked hypotrichosis with nearly complete anodontia has been recorded in pedigree Canadian and German Holstein calves. The phenotype is inherited as a monogenic X-linked recessive trait. An RT-PCR assay was used to identify the causative large genomic deletion in the bovine EDA gene. The bovine EDA gene encodes ectodysplasin A, a membrane protein expressed in keratinocytes, hair follicles, and sweat glands, which is involved in the interactions between cell and cell and/or cell and matrix. A single-nucleotide polymorphism (SNP) at the 9(th) base of exon 8 in the EDA gene is located in the exonic splicing enhancers (ESEs) recognized by SR40 protein. Consequently, the spliceosome machinery is no longer able to recognize the sequence as exonic and causes exon skipping. The mutation determines the deletion of the entire exon (131 bp) in the RNA processing, causing a severe alteration of the protein structure and thus the disease. Analysis of the SNP allows the identification of carriers that can transmit the disease to the offspring.

Chapter 16  ■ Diseases of the Skin, Eye, Conjunctiva, and External Ear
when red animals, particularly of the Simmental breed and carrying the mutation responsible, are crossed with black or black-pied cattle. Inherited as a dominant trait, 50% of progeny of such matings have black diluted to a charcoal- or chocolate-colored coat and variable degrees of hypotrichosis. This condition also occurs in offspring of Hereford–Friesian crosses and is evident as dilution of the dark coat color and hypotrichosis affecting particularly the tail switch when the hair of the tail is colored (hence “rat tail”). White hair is not affected.

The abnormality is in the premelanosome protein 17 gene (PMel17), and affected animals are heterozygous. Cattle that express the syndrome must have at least one dominant gene for black color and be heterozygous at the other locus.

A study of the inheritance of the abnormality found that all rat-tail calves were sired by Simmental bulls and were from cows with various percentages of Angus breeding. The abnormality had no effect on birth weight, weaning weight, or gain from birth to weaning. However, rat-tail calves had significantly lower rates of gain during the winter months from weaning to yearling than non-rat-tail calves. Histologically, there are enlarged, irregularly distributed, and clumped melanin granules in the hair shafts, which are asymmetric, short, curled, and small. The scale surface is rough and pitted, and scale fails to form in some areas.

**INHERITED HAIR-COAT-COLOR-LINKED FOLLICLE DYSPLASIA**

Some “bucks skin”-colored follicular dysplasia occurs in so-called “Portuguese” Holstein cattle, a grade variant of Red Holsteins with a tan color instead of the red. This defect consists of a coat-color-linked hair follicle dysplasia, in which the colored hairs are shorter and less lustrous than the white hair, making the coat much finer and smoother. Test matings seem to confirm an autosomal-dominant inheritance.

A black-hair-colored follicular dysplasia is also recorded in Holstein cattle. Patches of hair loss varying from hypotrichosis to complete alopecia occur in a random fashion but only on black areas. Follicular dysplasia is evident in biopsy samples. The abnormality persists for the life of the animal and is of cosmetic importance only. An inherited etiology is assumed.

A follicular dysplasia in a mature Brangus-cross cow and a mature Angus cow has been described. Adult-onset alopecia occurred, and skin biopsy revealed follicular distortion and atrophy, with melanin clumping in follicular epithelium, hair bulb matrix cells, hair shafts, and infundibular keratin.

---

**INHERITED BIRTHCOAT RETENTION**

Inherited birthcoat retention is recorded in Merino and Welsh mountain sheep and characterized by a coat of hairy medul- lated fibers in contrast with the nonmedul- lated wool fibers of the normal sheep fleece.

---

**INHERITED LEUKODERMA**

The Arab fading syndrome commences in young horses, in particular families of Arab horses, as round, unpigmented patches of skin around the lips, eyes, perineum, and preputial orifice. Some cases recover spontaneously, but the blemish is usually permanent.

---

**INHERITED EPIDERMAL DYSPLASIA (BALDY CALVES)**

This is a lethal defect of Holstein–Friesian calves inherited as an autosomal-recessive character. The calves, most commonly heifers, are normal at birth but at 1 to 2 months of age begin to lose condition in spite of good appetites. The skin over most of the body is slightly thickened, scaly, and relatively hairless. There are also patches of scaly, thickened, and folded skin, especially over the neck and shoulders, and hairless, scaly, and often raw areas in the axillae and flanks and over the knees, hocks, and elbow joints. The skin over the joints is immov- able. There is usually alopecia around the base of the ears and eyes. The tips of the ears are curled backward. The horns fail to develop, and there is persistent slobbering, although there are no mouth lesions. The hooves are long, narrow, and pointed because of gross overgrowth of the walls; these and stiffness of joints cause a shuf- fling, restricted gait. Calves assume a recumbent posture most of the time. Severe emaciation leads to destruction at about 6 months of age.

Histologic changes in the skin include acanthosis, hyperkeratosis, and patchy neutrophil invasion. The similarity of this condition to inherited parakeratosis and to experimental zinc deficiency suggests an error in zinc metabolism, but treatment with zinc had no effect on the course of the disease.

**INHERITED DYSERYTHROPOIESIS–DYSKERATOSIS**

See “Inherited Blood Diseases.”

---

**INHERITED CONGENITAL ABSENCE OF THE SKIN**

**Epitheliogenesis Imperfecta (Aplasia Cutis)**

Absence of mucous membrane or, more commonly, absence of skin over an area of the body surface has been recorded at birth in pigs, calves, lambs, and foals. There is complete absence of all layers of the skin in patches of varying size and distribution. In cattle the defect is usually on the lower parts of the limbs and sometimes on the muzzle and extending onto the buccal mucosa. The disease is best known in Holstein–Friesians, but is also recorded in Japanese Black, Short-horn, Sahiwal, and Angus cattle. In pigs the skinless areas are seen on the flanks, sides, back, and other parts of the body, and these areas develop into ulcers and are often secondarily infected, necessitating customary slaughter. The defect is usually incompatible with life, and most affected animals die within a few days. Inheritance of the defect in cattle is conditioned by a single auto- somal-recessive gene, and pigs are thought to have the same genetic cause. Tissue-cultured fibroblasts from affected animals produce subnormal amounts of collagen and lipids.

**REFERENCE**

---

**Familial Acantholysis**

Suspected of being an inherited disease, familial acantholysis in Angus calves is character- ized by defective collagen bridges in the basal and prickle layers of the epidermis so that skin, normal at birth, is subsequently shed at the carpal and metacarpophalangeal joints and coronet, and there is separation of the horn at the coronet.

**Epidermolysis Bullosa**

Epidermolysis bullosa is a congenital disease of Suffolk and South Dorset Down sheep and Simmental and Brangus calves and is character- ized by the formation of epidermal bullae in the mouth and on exposed areas of skin, such as the extremities of the limbs, muzzle, and ears, leading to shedding of the covering surface and separation of the horn from the coronet. Lesions may be present at birth. Simmental calves grow poorly, have hypotrichosis, and suffer repeated breaks in the skin, apparently as a result of an abnor- mal susceptibility to trauma. Most calves die, but some survive and the lesions subside. In Simmentals the disease is inherited as an autosomal-dominant trait. The disease in Brangus calves is very similar to familial acantholysis in Angus cattle.

The severe form of Herlitz junctional epi- dermolysis bullosa, which occurs in humans, has been recorded in foals of the French draft horse breeds. A mutation in the LAMC2 gene is responsible for the defect. Affected foals were born with skin blistering and skin and
Diseases of the Skin, Eye, Conjunctiva, and External Ear

Chapter 16 - Diseases of the Skin, Eye, Conjunctiva, and External Ear

Hamilcar, and cattle is a result of a mutation in the gene, encoding for laminin gamma 2 protein, which occurs in Scottish Blackface and Welsh mountain sheep. The lesions are not present at birth but become apparent at 2 to 4 days of age when there is sloughing of skin of the lamb, the accessory digits, the ear pinna, and the epidermal layers of the cornea and buccal mucosa, especially the dorsum of the tongue. There is also an absence of head horn and a separation of hoof horn from the coronet. Pieces of horn become completely detached, exposing the red corium below, hence the term “red foot.” The cutaneous and mucosal lesions often commence as blood-filled or fluid-filled blisters. The corneal lesions are similarly the result of sloughing of epidermal layers. Although the cause is unknown, there are indications that it is inherited.

INHERITED HYPERBILIRUBINEMIA AND PHOTOSENSITIZATION

An inherited photosensitization with hyperbilirubinemia has been observed in Southdown sheep in New Zealand and the United States, and in Corriedales in California. It is inherited as an autosomal-recessive trait. Liver insufficiency is present, but the liver is histologically normal. Phyloerythrin and bilirubin excretion by the liver is impeded, and the accumulation of phyloerythrin in the bloodstream causes the photosensitization. There is also a significant deficiency in renal function. Symptomatic treatment of photosensitization and confining the animals indoors may enable the lambs to fatten to market weight. The persistent hyperbilirubinemia is accompanied by an inability of the kidneys of these sheep to concentrate urine and the eventual death of the sheep from renal insufficiency.

Affected sheep live for several years if they are protected from sunlight and tend to die of renal failure associated with progressive fibrosis of the kidneys. A similar disease in Corriedale sheep in California is inherited as an autosomal-recessive trait. The functional defect is not in the uptake of unconjugated bilirubin and phyloerythrin, but rather its excretion from liver into bile. It affects lambs as they begin to eat pasture. Lambs live until 6 months of age if provided with some shade. There is also marked melanin-like pigmentation of the liver.

These two diseases are examples of the involvement of external environmental disease factors with a genetic disease: a diet of green forage (chlorophyll) and sunlight working in concert with the inborn error of metabolism to induce photosensitization.

INHERITED CONGENITAL ICHTHYOSIS (FISH-SCALE DISEASES)

Congenital ichthyosis is a disease characterized by alopecia and the presence of plates of horny epidermis covering the entire skin surface. It has been recorded only in Holstein and Norwegian Red Poll and probably in Brown Swiss calves among the domestic animals, although it occurs also in humans.

The newborn calf appears to be either partly or completely hairless, and the skin is covered with thick, horny scales separated by fissures that follow the wrinkle lines of the skin. The scales may penetrate deeply and become ulcerated. There are plenty of normal hair follicles and normal hairs, but these are lost in the areas covered by the growth of scales. A skin biopsy section will show a thick, tightly adherent layer of keratinized cells. The disease is incurable, and although it may be compatible with life, most affected animals are disposed of for esthetic reasons. The defect has been shown to be hereditary and to result from the influence of a single recessive gene.

INHERITED DERMATOSIS VEGETANS OF PIGS

Inherited dermatosis vegetans of pigs appears to be conditioned by the inheritance of a recessive, semilethal factor. Affected pigs may show defects at birth but in most instances lesions appear after birth and up to 3 weeks of age. The lesions occur at the coronets and on the skin. Those on the coronets consist of erythema and edema with a thickened, brittle, uneven hoof wall. Lesions on the belly and inner surface of the thigh commence as areas of erythema and become wart-like and covered with gray-brown crusts.

Many affected pigs die, but some appear to recover completely. Many of the deaths appear to be a result of the giant-cell pneumonia that is an essential part of the disease. The pathology of the disease indicates that it is the result of a genetic defect that selectively affects mesodermal tissue. It is known to have originated in the Danish Landrace breed.

DERMATOSPARAXIS (HYPERELASTOSIS CUTIS)

Dermatosparaxis is an extraordinary fragility of skin and connective tissue in general, with or without edema. It is probably inherited as a recessive character. It occurs in cattle, in horses (see “Hereditary Equine Regional Dermal Asthenia”), in Finnish and White Dorper sheep, and in a mild form in Merino sheep. The latter is inherited as a...
simple autosomal-recessive trait. The skin is hyperelastic, as are the articular ligaments; marked cutaneous fragility, delayed healing of skin wounds, and the development of papyraceous scars are also characteristic. Pieces of skin may be ripped off when affected sheep are being handled. In horses the skin in some parts of the body is thinner than elsewhere (e.g., the skin of the ventral abdomen) and the collagen bundles in the area are more loosely packed and are curved rather than straight. The proportion of acid-soluble collagen is also much higher in this abnormal skin. The disease involves a molecular defect of a collagen-binding protein and is related to a recognized problem in dogs and cats identified as “dominant collagen packing defect.”

Hereditary equine regional dermal asthenia is discussed under that heading in the following section. Ehlers–Danlos syndrome, recorded in Charolais and Simmental cattle, Quarter horses (cyclophilin-B gene independent), Warmblood foals (cyclophilin-B gene independent), and Rippolesa sheep, is also characterized by extreme fragility of the skin and laxness of joints in the newborn. There is a defect in collagen synthesis, and histopathological findings include fragmentation and disorganization of collagen fibers. The disease in Warmblood foals is well recognized and is caused by a defect in the equine procollagen-lysine, 2-oxoglutarate 5-dioxygenase 1 (PLOD1, or lysyl hydroxylase 1) gene. Affected foals born at term have thin and friable skin, skin lesions on the legs and the head, and an open abdomen. Histologic examination reveals abnormally thin dermis and markedly reduced amounts of dermal collagen bundles, with loose orientation and abnormally large spaces between deep dermal fibers. A genetic test is available and should be considered for Warmblood mares that abort, have stillborn foals, or have foals with characteristic lesions.

A case of dermal asthenia reported in a Warmblood in Australia was in a 6-week-old foal. Confirmatory genetic testing was not undertaken.

The syndrome has also been recorded in lambs. The skin was loose and present in excessive amounts, with folds over the carpal joints and lower regions of the legs. In some lambs, there may be separation of the epidermis from the dermis with blood-filled cavitations and intact skin that can be easily torn.

REFERENCES

INHERITED MELANOMA

Inherited cutaneous malignant melanoma is found in National Institute for Health (NIH miniature) and Sinclair miniature swine. Its expression is associated with two genetic loci, one of which is associated with the swine major histocompatibility complex. Familial melanomas have also been recorded in members of successive litters from an individual Duroc × Slovak White sow.

INHERITED HYPERHIDROSIS

Inherited hyperhidrosis, a condition characterized by excessive sweating and thought to be inherited, is recorded in beef Shorthorn calves. The syndrome includes conjunctivitis, with some cases progressing to complete opacity of the cornea, heavy dandruff, and persistent wetness of the hair coat.

LAVENDER FOAL SYNDROME

Lavender foal syndrome is a congenital, inherited, autosomal-recessive disease of Egyptian Arab foals characterized by an unusual dilute coat color and signs of neurologic disease evident at birth. Additional details provided in Chapter 14 (“Diseases of the Nervous System”).

INHERITED EQUINE REGIONAL DERMAL ASTHENIA (HYPERELASTOSIS CUTIS)

Hereditary equine regional dermal asthenia (HERDA) is a degenerative skin disease caused by an autosomal-recessive trait of Quarter horses and related breeds attributable to a mutation in Equus caballus chromosome 1 (ECA1). The abnormality is a c.115G>A mutation in the peptidyl-propyl isomerase cis-trans B (PPIB) gene. Resultant abnormalities in cyclophilin B cause a two-to-threefold reduction in the tensile strength and elastic modulus of skin of affected horses.

The allele frequency in 651 elite American Quarter horses is estimated at 2.9%, and carrier detection at 4.8% in elite American Quarter horses. The allele frequency in 651 elite American Quarter horses is estimated at 2.9%, and carrier detection at 4.8% in elite American Quarter horses. Inheritance of affected animals and those not carrying the disease, bearing in mind that it is an autosomal-recessive disease. However, the high prevalence of the disease in some uses of horses (cutting horses) suggests selection for the trait, perhaps because it is closely associated with a desired phenotype.

REFERENCES

DERMATOSIS VEGETANS

Dermatosis vegetans is a rare condition of pigs first described in 1967 and originating in the Swedish Landrace import to the United Kingdom. It is governed by a semithal factor with autosomal-recessive inheritance. Often only two to three pigs per litter are affected. Pigs will often first show a decline in growth and then die after 7 to 8 weeks, but some occasionally recover. It is seen as three clinical conditions:

• There is an erythematous maculopapular dermatitis often present at birth or around 2 to 3 weeks of age. Lesions are found on the abdomen or inside of the thighs and may spread and pass through a Pityriasis-like phase. After 5 to 8 weeks the lesions become thickened and covered with crusts.

• The second group of lesions, usually present at birth, occur in the form of “clubfeet,” with swelling and erythema and defective horn on the walls, sole, and bulb of the foot.
• The third major clinical condition is respiratory dysfunction, which is caused by a giant-cell pneumonia. It is characteristic of the condition in pigs older than 1 week of age. There are granules present throughout the lung, and these heal by fibrosis. The differential diagnoses include pityriasis rosea, chronic exudative dermatitis, and vitamin deficiencies.

There is no treatment, and control is through culling of breeding stock that have been affected.

FURTHER READING

PUSTULAR PSORIIFORM DERMATITIS (PITYRIASIS ROSEA)
The condition of pityriasis rosea in humans is not like the condition in pigs; thus, pustular psoriiform dermatitis (PPD) is a much better term for what is in fact a ring or rings of keratinized cells that are erythematous initially and raised surrounding a central crater. The condition occurs in young pigs, 3 to 14 weeks of age, is self-limiting, and is usually gone by 4 to 6 weeks following appearance.

The etiology is thought to be an autosomal-dominant gene with incomplete penetrance. It is definitely familial and may be more common in Landrace.

Clinically, there is a superficial accumulation of scales in a dry, lusterless coat.

Pityriasis scales are accumulations of keratinized epithelial cells, sometimes softened and made greasy by the exudation of serum or sebum. Overproduction, when it occurs, begins around the orifices of the hair follicles and spreads to the surrounding stratum corneum. The lesions are not itchy.

Diagnosis is based on age, clinical appearance, lack of itching and failure to demonstrate mites or ringworm on skin scrapings. Skin biopsy also helps in that there is an epidermal hyperplasia and superficial perivascular dermatitis.

Pityriasis is identified by the absence of parasites and fungi on skin scrapings.

DIFFERENTIAL DIAGNOSIS
Differential diagnosis of excessive bran-like scales on the skin, characterized by overproduction of keratinized epithelial cells, can be caused by deficiency of B vitamins, especially riboflavin and nicotinic acid, or linoleic acid and possibly other essential fatty acids, and poisoning by iodine. It can also be secondary to flea, louse, and mange infestations and ringworm infections. Also, hyperkeratosis and parakeratosis conditions should be considered.

TREATMENT
Treatment does not appear to have any effect, and self-cure is the norm. If there is secondary infection under conditions of bad hygiene, supportive therapy may help. Culling of the breeding stock producing the affected stock is advisable.

Eye and Conjunctival Diseases
CONJUNCTIVITIS AND KERATOCONJUNCTIVITIS
Conjunctivitis refers to inflammation of the covering membrane of the eye, including the orbit and the inner surface of the eyelids. The inflammation commonly extends to layers below the conjunctiva, referred to as keratoconjunctivitis.

ETIOLOGY
Causes of inflammation of the conjunctiva can be various and include bacterial, viral, parasitic, or mycotic infections; allergic and immune reactions; conjunctival foreign bodies; and trauma.

Specific Conjunctivitis
Cattle
• Infectious bovine keratoconjunctivitis (IBK, pinkeye) a common and highly contagious form of keratoconjunctivitis that is associated with Moraxella bovis (see also “Infectious Bovine Keratoconjunctivitis”)
• Listerial keratoconjunctivitis and uveitis (silage eye) is associated with Listeria monocytogenes (see also “Listerial Keratoconjunctivitis”)
• Ulcerative blepharitis and conjunctivitis associated with Moraxella bovoculi in cattle3

Sheep and Goats
• Infectious keratoconjunctivitis (pinkeye) of sheep and goats associated with Mycoplasma conjunctivae and Chlamydia psittaci.

Pigs
• Chlamydial-associated conjunctivitis in pigs associated with Chlamydia spp

Horses
• Eosinophilic keratoconjunctivitis of unknown etiology5
• Conjunctival habronemiasis caused by larval invasion of Habronema spp.
• Ocular onchocerciasis associated with microfilaria of Omphocerca spp. The causative association between these microfilaria and equine ocular disease is under debate.

• Fungal keratomycosis in foals and adult horses; Aspergillus flavus has been identified in some cases.

A. fumigatus is listed among the causes of mycotic keratitis in animals. Most cases begin as traumatic injuries with secondary infections or begin in eyes treated for long periods with broad-spectrum antibiotics.

Secondary Diseases in Which Conjunctivitis Is a Significant but Secondary Part of the Syndrome
Cattle
• Bovine viral diarrhea
• Malignant catarrhal fever
• Rinderpest
• Infectious bovine rhinotracheitis
• Viral pneumonia as a result of various viruses
• Bluetongue (specifically BTV-8)
• Besnoitiosis

Sheep
• Bluetongue

Pigs
• Swine influenza
• Inclusion-body rhinitis

Horses
• Equine viral arteritis
• Equine viral rhinopneumonitis

Nonspecific Conjunctivitis
Nonspecific conjunctivitis refers to inflammation caused by foreign bodies or chemicals, or secondarily as exposure keratitis, and conjunctivitis/keratitis in paralysis of eyelids as in laceriosis. Ant-bite conjunctivitis occurs in similar circumstances.

CLINICAL FINDINGS
Blepharospasm and weeping from the affected eye are the initial signs. Watery tears are followed by mucopurulent, then purulent ocular discharge if the lesion extends below the conjunctiva. Varying degrees of opacity of the conjunctiva may develop, depending on the severity of the inflammation. In the severest lesions there is underrunning of the conjunctiva with pus accompanied by vascularization of the cornea. During the recovery stage there is often long-lasting, diffuse opacity of the eye and terminally a chronic white scar in some cases.

CLINICAL PATHOLOGY
In herd or flock outbreaks, conjunctival swabs and/or scrapings should be taken for culture and examination of cells using special stains and histologic techniques.

LISTERIAL KERATOCONJUNCTIVITIS AND UVEITIS (SILAGE EYE, BOVINE IRITIS)

SYNOPSIS

**ETIOLOGY**

*Listeria monocytogenes* is the only causative agent associated with listerial conjunctivitis, which is a condition specifically affecting the eye. It is unrelated to systemic infection with *L. monocytogenes* causing the classic forms of listeriosis (see also “Listeriosis”). Local uveitis associated with *L. monocytogenes* has been reported to occur in cattle, sheep, horses, fallow deer, and humans.

*Listeria* is a ubiquitously occurring gram-positive, asporogenous bacterium easily surviving in organic material at temperatures between 3° and 45° (37° to 113°F) and at pH as low as 3.8 in an aerobic environment. Silage of poor quality that is either not conserved anaerobically or not sufficiently acidic facilitates growth of *Listeria*. Listerial conjunctivitis is almost invariably associated with feeding poor-quality silage either directly as big bales or ring feeders.

**EPIDEMIOLOGY**

The disease has been reported to occur in different parts of the world, although most cases are recorded in the United Kingdom, probably because of greater awareness of the existence of this condition. The disease incidence is highest in late fall, winter, and early spring when animals are kept inside and fed silage. Frequently only individual cases occur, but outbreaks with morbidity rates far above 25% have been reported. In the United Kingdom an overall animal incidence of 3.4% and an average incidence in affected herds of 66.5% was reported.

**SOURCE OF INFECTION**

Because most cases of listerial keratoconjunctivitis have been linked to silage feeding, grass silage of poor quality contaminated with *L. monocytogenes* is widely accepted as the primary source of infection.

**CLINICAL FINDINGS**

Although in most cases only one eye is affected, bilateral lesions can occur. Systemic disease is usually absent. First clinical signs include increased lacrimation and catarrhal conjunctivitis with photophobia and blepharospasm. Inflammation of the cornea, starting at the limbic border and spreading centrifugally, results in a bluish-white opacity of the cornea. Corneal ulcers are uncommon. In advanced cases focal aggregation of fibrin accumulating in the anterior eye chamber may become visible as white foci beneath the corneal surface. The course of the disease, which is considered to be self-limiting, is between 1 and 3 weeks when left untreated.

**CLINICAL PATHOLOGY**

The tentative diagnosis can be made based on the clinical presentation in combination of the history (season and silage feeding) but should be confirmed by identifying *L. monocytogenes* from swab obtained from affected eyes. Cultures or PCR are used to identify the pathogen.

**DIFFERENTIAL DIAGNOSIS**

**Infectious bovine keratoconjunctivitis (IBK)** has a different seasonality (peaks occurring in the warm season of the year). Evaluation of housing and feeding system may provide further clues to differentiate between these conditions. Corneal ulceration is a common finding with IBK but not with listerial conjunctivitis.

**Pasturella multocida** (capsular type A) has been isolated from the eyes of housed heifers that experienced outbreaks of severe keratitis with severe loss of corneal stroma within 72 hours of onset.

**Mycoplasma bovis** has been isolated from the eyes of steers with an outbreak of severe conjunctivitis with corneal opacity and ulceration, with disease being followed by serologic conversion in affected animals. Involvement of the eyelids with marked swelling was prominent. Conjunctivitis is prominent in other mycoplasmal infections that produce keratoconjunctivitis.

**Chlamydial keratoconjunctivitis** presents with identical clinical findings but has a protracted course despite treatment and a higher morbidity. *Chlamydophila* DNA can be detected by polymerase chain reaction (PCR) in conjunctival swabs. This disease is a possible zoonosis.

**Infectious bovine rhinotracheitis**

**Bovine malignant catarrhal fever**

**Bovine viral diarrhea**

**Bluetongue (BTV-8)**

**Thelaziasis**

**Squamous-cell carcinoma**

**TREATMENT**

A number of empirical treatment approaches have been reported, with variable outcome. Listerial keratoconjunctivitis is considered to be a self-limiting disease, and it is difficult to determine whether reported treatments were effective or if recovery was primarily a result of removing access to the primary cause.

Proposed treatments include the topical use of eye ointments containing oxytetracycline or cloxacillin as well as the parenteral administration of repeated doses of oxytetracycline, procaine-penicillin, or ampicillin. The use of topical or subconjunctival dexamethasone application has been proposed, with variable outcome.

**TREATMENT**

**Topical treatment:**

- Benzathine cloxacillin eye ointment (250 mg q48) (R-2)
- Oxytetracycline eye ointment (q24h) (R-2)

**Systemic treatment:**

- Procaine-penicillin-G (40,000 IU/kg q24 IM) (R-3)
- Oxytetracycline (10 mg/kg q24h IM) (R-3)
- Ampicillin (10 mg/kg q24 SC) (R-3)

**CONTROL**

The most important control measures are to avoid feeding poor-quality silage and to use
feeding systems that provide feed at a height that is below the animals’ heads.

INFECTIONBOVINE KERATOCONJUNCTIVITIS OF CATTLE (PINKEYE, BLIGHT)

SYNOPSIS
Etiology Moraxella bovis is the primary infectious agent. Pili and hemolysin are the main virulence factors. Solar radiation, flies, and dust are contributing factors.

Epidemiology Cattle of all ages are susceptible. Source is asymptomatic carrier cattle, with transmission by媒介 contamination and by flies. More common in summer months. Usually multiple cases in a herd.

Clinical findings Conjunctivitis, lacrimation, blepharospasm, photophobia, corneal edema, corneal ulceration.

Diagnostic confirmation Culture.

Control Current vaccines have limited efficacy. Fly control.

ETIOLOGY
Hemolytic Moraxella bovis is the only infectious agent for which Koch’s postulates have been established for infectious bovine keratoconjunctivitis (IBK), although other organisms, such as Moraxella ovis, Moraxella bovoculi, Neisseria spp., Mycoplasma spp., and Chlamydia spp. have been implicated.1 Experimental infections in calves and studies on corneal tissue culture show a great variation in virulence between strains. Two virulence factors are determinants of cause in clinical disease. These are the presence of fimbriae, so-called pili, on the bacterial surface and the production of β-hemolysin. Other contributing virulence factors include phospholipases, iron acquisition systems, and hydrolytic and proteolytic enzymes.2 M. bovis has serologically distinct shared and variable pili epitopes, and strains can be distinguished by their pili antigens into seven distinct serogroups. There are two distinct types of pilus, I and Q (formerly α and β). Q pili mediate bacterial adhesion to the cornea and the establishment of infection by preventing removal of the pathogen by the continual flushing effect of ocular secretions and the mechanical action of blinking. Beta-hemolysin is cytotoxic and produces corneal damage. In some outbreaks of pinkeye more than one serotype can be isolated from affected eyes.

In addition to M. bovis, other pathogens, such as M. bovoculi, M. ovis, Chlamydia spp., Neisseria spp., Mycoplasma spp., Acholoplasma spp., and viruses have been identified as common participants and are likely to contribute to the development of clinical disease. Infectious bovine rhinotracheitis virus causes ocular disease in its own right, but it may also be involved with M. bovis in causing the more severe disease. Clinical disease in experimentally induced IBK has been shown to be more severe when the calves are concurrently given a modified live infectious bovine rhinotracheitis virus vaccine.

 Conjunctival infection with M. bovoculi has been proposed to play a role in the pathophysiology of IBK by some authors.2,3

The evidence in support of this assumption is inconsistent. A clinical study consistently demonstrated the development of corneal ulcers after inoculation with hemolytic M. bovis but not with M. bovoculi.3 Branhamella ovis causes a severe conjunctivitis in sheep and goats and is also recorded from outbreaks of keratoconjunctivitis in cattle in Israel; it may be a cause of vaccine breakdown in other countries.

Because the naturally occurring disease is usually much more severe than that produced experimentally, factors other than infectious agents have been examined. Solar radiation, flies, and dust have been shown to have an enhancing effect. Cultural characteristics of the organisms isolated from the conjunctiva can change with the level of solar ultraviolet radiation.

EPIDEMIOLOGY
Occurrence
The disease occurs in most countries of the world. Although it can occur in all seasons, it is most common in summer and autumn. The prevalence and severity of the disease vary greatly from year to year, and it may reach epizootic proportions in feedlots and in cattle running at pasture. There is no mortality, and cases in which there is permanent blindness or loss of an eye are rare. However, the morbidity rate can be as high as 80%, with the peak infection rate at weeks 3 to 4 of the outbreak. Severe outbreaks can be experienced in winter, especially if the cattle are confined in close quarters, such as barns or intensive feedlots.

Source of Infection
Cattle are the only known reservoir, and the organism is carried on the conjunctiva and also in the nares and vagina of cattle. Persistence of the disease from year to year is by means of infected but asymptomatic animals, which can act as carriers for periods exceeding 1 year. Receptors for I-pili may be found on tissues other than the cornea and facilitate colonization of noncorneal tissue and inapparent infection, and the organism can switch from expression of one pilus type to the other.

Environmental Risk Factors
The disease incidence shows a clear seasonality, with the highest incidence in the warmer months of the year. This seasonal expression has been associated with prolonged exposure of the eye to UV radiation, the increased fly population, and long grass.1 The exposure of the eye to UV radiation increases the susceptibility to the disease and the severity of signs resulting from it. The face fly (Musca autumnalis) and Asian face fly (Musca bezzii), because of feeding preference for the area around the eyes, are important vectors.

Other environmental factors, such as dust, wind, and tall grass, can increase the disease incidence by causing mechanical irritation of the cornea.

Transmission
Transmission is thought to be by means of flies contaminated by the ocular and nasal discharge of infected cattle. Under experimental conditions, transmission is unusual in the absence of flies and occurs generally in their presence. M. autumnalis is known to remain infected for periods of up to 3 days. M. bovis can be isolated from the crops of M. autumnalis that have fed on the eyes of infected cattle.

Animal Risk Factors
Only cattle are affected, the young being most susceptible, but in a susceptible population, cattle of all ages are likely to be affected.

It is commonly observed that there is a much higher prevalence of the disease in B. taurus cattle as distinct from B. indicus cattle, and the severity and proportion of bilateral infections is much greater in B. taurus cattle than in crossbreeds. Hereford and Hereford crossbreed cattle have a significantly higher risk of developing IBK than other breeds or crossbreeds not containing Hereford.3 This higher predisposition is thought to be based on a relationship between rate and severity of infection and the degree of eyelid pigmentation; eyes with complete pigmentation are less affected.

Immune Mechanisms
Previous infection appears to confer a significant immunity that lasts through to the next season, when further reinfection, usually with minimal clinical disease, confers further immunity. Lacrimal secretions contain antibody, and antibody directed against the pilus antigens of M. bovis will prevent adherence of the organism to the cornea. In experimental infections, significant protection against challenge can be
achieved by prior vaccination with pilus antigens of the homologous strain.

However, there is antigenic diversity in pili from different strains of *M. bovis*, and vaccines composed of pili from one strain only confer protection to challenge with organisms of the same serogroup. Further, *M. bovis* in the eye can switch their pilus antigenicity in response to antibody presence and render monovalent vaccines ineffective. A polyvalent vaccine might provide protection, but polyvalent vaccines are less immunogenic than monovalent vaccines because of antigenic competition.

**Economic Importance**

Infectious bovine keratoconjunctivitis is a prominent disease in surveys of the predominant diseases in cattle and is considered the economically most important ocular disease of cattle. Losses result from reduced weight gain or loss of body condition; loss of milk production; costs of drugs, labor, and veterinary care; and loss of value of show animals. The conditions under which calves are reared can affect the importance of the disease. In veal calves, the disease may have no measurable effect on growth, but in calves running at pasture it can result in a significant reduction of weaning weight. Occasionally, animals become completely blind, and those at pasture may die of starvation. Animal welfare presents an increasing concern.

**PATHOGENESIS**

As mentioned, only pilated and hemolytic strains of *M. bovis* are pathogenic to cattle (determinant virulence factors). Attachment of *M. bovis* to the corneal epithelium requires the presence of pili and Q-piliated organisms that are more infectious than I-piliated strains. Hemolysins produced by these virulent strains are cytotoxic and cause the development of corneal ulcers by destroying corneal epithelial cells.

Microscopic corneal erosions are present within 12 hours of infection and occur at this time in the absence of a significant inflammatory response, indicating that the initial production of the corneal ulceration is a result of the direct cytotoxic activity of the organism. This is followed by focal loss of corneal epithelium, degeneration of kerocytes, and invasion of the corneal stroma with fibrillar destruction. An inflammatory reaction occurs several days postinfection and results in enlargement of the corneal ulcers with deeper stromal involvement, corneal edema, and corneal neovascularization. The lesions are localized in the eye, and there is no systemic infection.

**CLINICAL FINDINGS**

An incubation period of 2 to 3 days is usual, although longer intervals, up to 3 weeks, have been observed after experimental introduction of the bacteria. Injection of the corneal vessels and edema of the conjunctiva are the early signs and are accompanied by a copious watery lacrimation, blepharospasm, photophobia, and, in some cases, a slight to moderate fever with fall in milk yield and depression of appetite.

In 1 to 2 days, corneal edema presenting as a small opacity appears in the center of the cornea, and this may become elevated and ulcerated during the next 2 days, although spontaneous recovery at this stage is quite common. With progressive disease the opacity becomes quite extensive, and at the peak of the inflammation, about 6 days after signs first appear, it may cover the entire cornea. The color of the opacity varies from white to deep yellow (Fig. 16-10). As the acute inflammation subsides, the ocular discharge becomes purulent and the opacity begins to shrink, complete recovery occurring after a total course of 3 to 5 weeks.

One or both eyes may be affected. The degree of ulceration in the early stages can be readily determined by the infusion of a 2% fluorescein solution into the conjunctival sac, the ulcerated area retaining the stain.

About 2% of eyes have complete residual opacity, but most heal completely with a small, white scar persisting in some. In severe cases the cornea becomes conical in shape, there is marked vascularization of the cornea, and ulceration at the tip of the swelling leads to underrunning of the cornea with bright yellow pus surrounded by a zone of erythema. These eyes may rupture and result in complete blindness.

A proportion of cases will develop minimal clinical lesions and heal spontaneously, and the severity of clinical disease can also vary between outbreaks.

**CLINICAL PATHOLOGY**

The organism can be identified by culture or fluorescent antibody. The hemolytic form of the bacterium is noticeably more pathogenic than the nonhemolytic form. Serum agglutinins (1:80 to 1:640) are present 2 to 3 weeks after clinical signs commence, and a modified gel diffusion precipitin test is capable of detecting *M. bovis* antibodies. An ELISA test is also used for antibody detection in experimental studies; however, neither agglutinating antibody nor antibody detected by ELISA correlates well with individual animal resistance to infection. There is little indication for serologic examinations in clinical practice. Necropsy examinations are not usually necessary.

**DIFFERENTIAL DIAGNOSIS**

- **Traumatic conjunctivitis** is usually easily differentiated because of the presence of foreign matter in the eye or the conjunctival sac or evidence of a physical injury.
- **Pasteurella multocida (capsular type A)** has been isolated from the eyes of housed heifers that experienced outbreaks of severe keratitis with severe loss of corneal stroma within 72 hours of onset.
- **Mycoplasma bovis** has been isolated from the eyes of steers with an outbreak of severe conjunctivitis with corneal opacity and ulceration, with disease being followed by serologic conversion in affected animals. Involvement of the eyelids with marked swelling was prominent. Conjunctivitis is prominent in other mycoplasmal infections that produce keratoconjunctivitis.

*Continued*
Listerial keratoconjunctivitis and uveitis
(silage eye) has a different seasonality and is associated with the use of specific feeding systems. Corneal ulcers are uncommon with listerial keratoconjunctivitis.

Chlamydial keratoconjunctivitis presents with identical clinical findings but has a protracted course despite treatment and a higher morbidity. Chlamydophila DNA can be detected by polymerase chain reaction (PCR) in conjunctival swabs. This disease is a possible zoonosis.

Infectious bovine rhinotracheitis
Bovine malignant catarrhal fever
Bovine viral diarrhea
Bluetongue (BTB-8)
Thelaziasis
Squamous-cell carcinoma

TREATMENT
Infectious bovine keratoconjunctivitis is frequently a self-limiting disease. Recovery commonly occurs without treatment, although early treatment will reduce the incidence of scarring of the eyes. Antibacterial treatment is commonly used, and mass treatment of the herd as opposed to just affected individuals may halt the occurrence of further cases. The route of administration is often determined by efficiency of the available treatment options, ease of access to the animals, availability of facilities to restrain animals for treatment, labor intensity of treatment, cost of the drug, and withhold times.

Topical Therapy
Early, acute cases respond to treatment with ophthalmic ointments and solutions containing antibiotics, but they need to be instilled in the conjunctival sacs at frequent intervals, which may be impractical under field conditions. The organism is sensitive to most antibiotics and sulfonamides but is resistant to erythromycin, lincomycin, and tylosin. The administration of an oil-based formulation of benzathine cloxacinil (250 to 375 mg per treatment dose) was found to be effective in therapy in controlled trials. Two doses, 72 hours apart, treating both eyes, even if only one eye is affected, is recommended. The use of the same ointment tube in affected and unaffected eyes is likely to present a risk for transmission of the pathogen.

Subconjunctival Therapy
The objective of subconjunctival treatment is to reduce the treatment dose and number of treatments while achieving higher antimicrobial tissue concentrations. Although subconjunctival therapy with antibiotic was found to be effective in treating IBK in several studies, it is under contentious debate if the treatment effect is obtained through direct diffusion of the drug to the surrounding tissue or rather through continuous leakage of the antibiotic onto the conjunctiva from the injection site. A small volume (1 to 2 mL) of procaine-penicillin G (300,000 IU/mL) is commonly injected under the scleral conjunctiva. Two treatments 48 to 72 hours apart were found to be equally effective as a single parenteral treatment with long-acting formulation of oxytetracycline (20 mg/kg). Therapy must be administered under the bulbar conjunctiva but was found to be ineffective if given in the superior palpebral conjunctiva. A controlled trial found that subconjunctival penicillin was effective in treatment, but recurrence was higher than with treatment with parenteral oxytetracycline, and mass treatment of calves with subconjunctival penicillin does not eliminate infection.

The intralapalpebral injection of 2 mL of a 10% oxytetracycline formulation was found equally effective as the systemic treatment with oxytetracycline (20 mg/kg). Transient swelling of the eyelids, leading to complete closure of the palpebral fissure, was observed in some cases after intrapalpebral injection of oxytetracycline. It was suggested that this transient closure of the eye may favor healing by protecting the cornea and conjunctiva.

Another technique for prolonging the maintenance of high levels of antibiotic in the conjunctival sac is the use of collagen implants impregnated with an antibiotic.

Parenteral Therapy
Parenteral treatment with two doses of long-acting oxytetracycline (20 mg/kg) 72 hours apart has been shown to ameliorate clinical signs of naturally occurring IBK. Recent studies have documented that florfenicol when administered either as a single subcutaneous dose of 40 mg/kg or two doses of 20 mg/kg administered 48 hours apart is effective for treatment of clinical IBK in calves. Healing times were shorter and relapses were fewer when using florfenicol instead of long-acting oxytetracycline for treatment of IBK in calves.

The use of tulathromycin, a macrolide antibiotic, was found to be effective to treat experimentally induced IBK in calves in one study. A single dose of 2.5 mg/kg resulted in faster healing and higher bacteriologic cure compared with untreated control animals.

Ancillary Therapy
Severe cases should be placed in a dark shelter out of direct sunlight. If housing is not possible, eye flap patches are available and effective. They are glued on above the eye and can be flipped up for medication of the eye.

When corneal ulceration has occurred, recovery is always protracted. The use of topical ophthalmic anesthetics combined with atropine administration may be indicated to minimize ciliary spasm and pain. Severe cases may require that the third eyelid be temporarily sutured across the globe of the eye for several days to promote healing. The use of NSAIDs should be considered in more advanced and severe cases.

CONTROL
Eradication or prevention of the disease does not seem possible under extensive range conditions because of the method of spread, but if fly control can be fitted into the farm’s management program this should significantly reduce the infection rate. Insecticide-impregnated eartags may help in the control of the disease but do not prevent it. In many herds the best that can be done is to keep animals under close surveillance and isolate and treat any cattle that show excessive lacrimation and blepharospasm. Cattle that have had the disease should not be mixed with those that have not until after the fly season.
**OVINE AND CAPRINE CONTAGIOUS OPHTHALMIA (OVINE AND CAPRINE INFECTIOUS KERATOCONJUNCTIVITIS, CONTAGIOUS CONJUNCTIVO-KERATITIS, PINKEYE IN SHEEP AND GOATS)**

**ETIOLOGY**

A variety of organisms have been isolated from the eyes of sheep and goats with keratoconjunctivitis. Some are primary pathogens and others secondary invaders. It is difficult to attribute a primary etiological cause to a single agent because all the putative causal organisms have also been isolated from the eyes of normal sheep. Mixed infections occur during an outbreak, with potential synergism between *Mycoplasma* spp. and other infectious agents. The management circumstances that lead to outbreaks of disease with each agent, and the clinical syndromes that result, are not sufficiently distinct to allow the differentiation of the various etiologies on clinical or epidemiological grounds. There have been limited studies on the relative prevalence of flock outbreaks of disease associated with the various putative causes, but there is a strong evidence to incriminate *Mycoplasma* spp., particularly *M. conjunctivae*, as the major cause in domesticated sheep and goats, and wild ruminants such as chamois, Alpine ibex, European mouflon, and Bighorn sheep.

**SYNOPSIS**

**Etiology** *Mycoplasma conjunctivae* is a significant cause, but other agents, in particular *Chlamydia pecorum*, *Moraxella ovis*, and other *Mycoplasma* spp., can produce clinically identical disease.

**Epidemiology** Rapid spread by contact with carrier animals. Usually occurs as outbreak in summer and when conditions are dry and dusty. Disease is most severe in weaned lambs.

**Clinical findings** Lachrimation, conjunctival hyperemia, pannus, neovascularization, iritis, keratitis in one or both eyes.

**Diagnostic confirmation** Clinical examination of the flock, exfoliative cytology, culture and polymerase chain reaction (PCR).

**Treatment** Topical or preferably parenteral tetracycline.

**Control** Avoid confinement and movement in dusty conditions. Fly control.

**REFERENCES**

**FURTHER READING**

POSTMA GC. *Chlamydophila psittaci* was isolated at a higher rate from diseased eyes, compared with asymptomatic eyes, in both sheep (80% and 68%, respectively) and goats (92% and 76%, respectively). A number of bacteria, including *Brachymellia (Neisseria) ovis*, *S. aureus* and *E. coli*, can be isolated from the eyes of animals with contagious ophthalmia, with rates of isolation from affected eyes higher than those from normal sheep. They have not always produced disease following experimental challenge. Consequently, they are considered to be secondary infections rather than having a primary causal role, exacerbating the lesions produced by the primary agent. *B. ovis* is considered a cause of follicular conjunctivitis. Similarly, *Moraxella bovis*, which is associated with contagious keratoconjunctivitis in cattle, has no apparent causal association with the disease in sheep, although it was isolated from clinical cases in goats in Nigeria. *Listeria monocytogenes* may be a primary cause of keratoconjunctivitis and iritis in sheep.

**EPIDEMIOLOGY**

**Occurrence**

The disease is widespread in sheep of all breeds in most countries. Recently weaned animals are often the most severely affected.

**Other Mycoplasmas**

Other *Mycoplasma* spp. are frequently identified in the eyes of sheep and goats with pinkeye. *M. arginini* and *Acholeplasma oculi* have been isolated from clinical cases of contagious ophthalmia. Infection with other mycoplasmas, such as *M. capricolum* subsp. *capricolum* and *M. mycoides* subsp. *capri*, can be accompanied by conjunctivitis, but other clinical signs, such as pneumonia, predominate.

**Chlamydia psittaci**

*Chlamydia psittaci (Colesiota conjunctivae) was initially incriminated as a cause of contagious ophthalmia in sheep and goats in South Africa and Australia. It has been isolated from outbreaks of keratoconjunctivitis in sheep in the United States and the United Kingdom, and the disease has been reproduced experimentally. The strains are related to those associated with polyarthritis in sheep rather than abortion. A rickettsial agent, *Rupricapra rupricapae*, has been isolated from keratoconjunctivitis in chamois (*R. tragis*) and ibex (*Capra ibex*) in the French Alps. In Egypt, *Chlamydia psittaci* was isolated at a higher rate from diseased eyes, compared with asymptomatic eyes, in both sheep (80% and 68%, respectively) and goats (92% and 76%, respectively). A number of bacteria, including *Brachymellia (Neisseria) ovis*, *S. aureus* and *E. coli*, can be isolated from the eyes of animals with contagious ophthalmia, with rates of isolation from affected eyes higher than those from normal sheep. They have not always produced disease following experimental challenge. Consequently, they are considered to be secondary infections rather than having a primary causal role, exacerbating the lesions produced by the primary agent. *B. ovis* is considered a cause of follicular conjunctivitis. Similarly, *Moraxella bovis*, which is associated with contagious keratoconjunctivitis in cattle, has no apparent causal association with the disease in sheep, although it was isolated from clinical cases in goats in Nigeria. *Listeria monocytogenes* may be a primary cause of keratoconjunctivitis and iritis in sheep.
Source of Infection and Transmission

The source of infection is infected or carrier animals. The disease is spread indirectly by flies, long grass, and dust contaminated by the tears of infected sheep, or directly by means of exhaled droplets or immediate contact. *M. conjunctivae* infects many wild small ruminant species and can be transmitted between domestic and wild animals.1,2

Risk Factors

The prevalence is highest during the warm, summer months and when conditions are dry and dusty and flies are abundant. The morbidity rate varies widely depending on seasonal conditions; it is usually about 10% to 15% but may be as high as 80%. Resistance to infection is reduced by other disease, poor nutrition, and adverse weather. Widespread outbreaks occur in some years where the disease contributes to poor growth and ill-thrift, presumably from reduced foraging ability, especially in young stock. Outbreaks during mating can reduce conception and lambing rates.

In many flocks at pasture the disease causes little disruption to grazing, and so only minor inconvenience. However, in other flocks, and in some years, higher morbidity, severe lesions, and detrimental effects on production occur. Clinical experience suggests that the incidence and the severity of the disease in an affected flock are increased by the stress, dust, and close contact associated with gathering and yarding of the flock. Thus a decision to treat during an outbreak can be associated with an apparent exacerbation of clinical disease.

PATHOGENESIS

Rapid onset of acute inflammation of the conjunctiva is followed by hyperemia of the sclera and paunch of the cornea. CLINICAL FINDINGS

Clinical findings are similar with all agents associated with the disease. There is conjunctivitis, lacrimation, and blepharospasm, followed by keratitis with cloudiness of the cornea and some increase in vascularity. There is profuse lacrimation, and thus initial signs in the flock may be a brown discoloration below the eye associated with dust accumulating on lacrimal discharges. Corneal opacity is initially most pronounced at the dorsal corneal–scleral junction. This is followed by vascularization, to produce a horizontal zone of opacity associated with an area of vertical-oriented vascularization in the upper area of the eye. In severe cases, the whole cornea is affected, and there may be corneal ulceration.

In flocks experiencing an outbreak, the disease in most sheep is mild if there are no complicating circumstances; the initial watery discharge from the eye becomes purulent, but recovery commences in 3 to 4 days and is complete at about 20 days. In some animals the cloudiness of the cornea may persist for several weeks or even permanently. Local ulceration of the cornea may cause collapse of the eyeball. One or both eyes may be affected, but many sheep have both eyes affected in outbreaks, and spread through the flock is rapid.

Conjunctivitis is followed by the development of granular lesions of follicular conjunctivitis on the palpebral conjunctiva and third eyelid, which are thought by some to be specific for infections involving *B. ovis*.

In goats, the disease is milder with little apparent ophthalmia or keratitis. A more severe keratoconjunctivitis than that associated with *M. conjunctivae*, and manifest with corneal edema, occurs in some outbreaks in goats, but its cause has not been established. All age groups are affected, and although the morbidity is usually 12% to 20%, it may reach 50%. Direct contact between animals appears to be necessary for spread of the infection, but the disease has not been transmitted experimentally. Conjunctivitis, opacity, vascularization, and sometimes ulceration of the cornea are accompanied by an ocular discharge and blepharospasm. In some goats there is severe corneal edema with intracorneal edema accumulating to a degree to produce corneal vesicles. In mildly affected goats, recovery begins in 4 to 7 days, but in severe cases, healing may not be complete for 2 to 4 weeks or longer.

CLINICAL PATHOLOGY

Scrapings can be taken for exfoliative cytology from the palpebral conjunctiva, preferably from early clinical cases. *Mycoplasma*, *Brachyspira*, and *Chlamydia* have characteristic morphology and can be demonstrated in Giemsa- or immunofluorescent-stained smears. Samples can also be submitted for culture identification, and paired serum samples can be submitted for examination for antibodies to *Chlamydia*.

The determination of the etiologic agent currently has limited significance to the subsequent approach to the control and treatment of the disease, and so is largely academic. However, conventional and real-time PCR can be used to detect *M. conjunctivae* and *Moraxella* spp., and PCR is a more sensitive way of detecting than culture.1,3

TREATMENT

A decision for treatment needs to be taken with consideration of the adverse effects on the disease of the associated movement and close yarding of the flock. Repeated treatments of sheep pastured under extensive grazing are impractical, and spontaneous recovery will occur within 3 weeks. Consequently, in extensive grazing conditions a decision for no treatment is often made.

A single intramuscular injection of long-acting tetracycline at 20 mg/kg halts further development of clinical conjunctivitis when given as clinical signs develop, and results in rapid clinical cure in animals affected with keratoconjunctivitis produced by *M. conjunctivae*. Florfenicol readily penetrates tear fluid, with doses greater than 20 mg/kg needed to provide minimum inhibitory concentrations against most *Mycoplasma* spp.7 However, neither parental or topical antibacterial treatment eliminates infection; thus, repeated infections in individual animals and recurrence of outbreaks in flocks are common. Where the etiology is not known and treatment is deemed desirable, tetracyclines administered either topically or parenterally, or topical treatment with cloxacillin or erythromycin ophthalmic ointments, have been shown to be of benefit.

CONTROL

Complete eradication of the disease is not attempted, but isolation of affected sheep and removal to grassier, less dusty pasture may reduce the rate of spread. Confine ment of affected sheep should also be avoided.

REFERENCES

DISEASES OF THE EYES ASSOCIATED WITH MYCOPLASMA SPP.

*Mycoplasma conjunctivae* is the etiologic agent causing infectious keratoconjunctivitis of small and wild ruminants (see also “Ovine and Caprine Infectious Keratoconjunctivitis”).

In cattle *M. bovoculi* is frequently isolated from conjunctival swabs without necessarily being associated with clinical disease. The recovery rate of *M. bovoculi* from eye swabs obtained from clinically healthy cattle and animals with conjunctivitis was approximately 40% in both instances. *M. bovoculi* was isolated more frequently from animals younger than 2 years of age than from older animals, whereas the disease incidence of infectious keratoconjunctivitis was similar in both age groups. The higher recovery rate of *M. bovoculi* in younger animals was explained...
by the development of immunity after initial infection.

Other Mycoplasma spp. that have been isolated from cattle with keratoconjunctivitis are *M. bovis*, *M. bovigenitalium*, *M. boviris*, *M. verecundum*, *Ureaplasma diversum*, *Acholeplasma laidlawii*, and *Acholeplasma oculi*, some of which have been incriminated as contributing to the development of infectious bovine keratoconjunctivitis.

**THELAZIASIS (EYEWORM)**

A number of species of the nematode genus *Thelazia* occur in the conjunctival sac and tear ducts of mammals throughout the world. *T. gulosa* and *T. skrjabini* are the main species in cattle in the New World, *T. rhodesi* is the commonest in the Old World, and *T. lucrinalis* is common in horses. They are thin worms up to 2 cm long. Infestation is often inapparent, but they may cause excessive lacrimation, photophobia, conjunctivitis, corneal opacity, keratitis, corneal ulceration, and abscess formation on the eyelids. In horses, this condition mainly occurs in young animals. One U.S. survey in Kentucky found 43% of horses up to 4 years old to be infected. In those species that have been studied, the life cycles are indirect, with muscid flies, particularly the face fly *M. autumnalis*, being the intermediate hosts. These flies deposit larvae on the conjunctiva when feeding on fluid around the eye. The disease is mainly seen in summer and autumn when the flies are active. It is usually more common in cattle and African buffalo than horses, and worms may be more abundant in beef than in dairy cattle. Eyeworm in cattle is differentiated from infectious keratoconjunctivitis by observing the adult worm in the conjunctival sac or demonstrating first-stage larvae in eye washings. Ivermectin (0.2 mg/kg, repeated three times at 1-month intervals) is active against worms in African buffalo. Ivermectin and doramectin are active against the adult worm in cattle, but anecdotal reports suggest that it may be less effective in horses.

**REFERENCES**

**“BRIGHT BLINDNESS” OF SHEEP CAUSED BY BRACKEN INGESTION**

A progressive retinal degeneration associated with ptaquiloside was observed in sheep kept for more than 3 years on pastures heavily infested with bracken in the United Kingdom, and the disease has been produced experimentally in sheep fed bracken. Affected sheep are blind, reluctant to move, but bright and alert. The pupils are dilated and show poor light and menace reflexes, and on ophthalmoscopic examination there is retinal degeneration. This degeneration may be observable in many more sheep than the clinically blind ones. Leukopenia is a characteristic.

**BOVINE OCULAR SQUAMOUS-CELL CARCINOMA**

Bovine ocular squamous-cell carcinoma (BOSCC), often referred to as “cancer eye,” is one of the most common neoplasms of cattle.

### SYNOPSIS

**Etiology** Genetic–environmental interaction. Lack of pigmentation around the eye and solar radiation.

**Epidemiology** One of most common neoplasms of cattle; mostly in beef cattle breeds with white on their heads (Hersford, Simmental) and lacking pigment around the eye; animals over 5 years of age. Solar radiation is a major risk factor.

**Signs** Precursor lesions; single or multiple plaques on eyelid or conjunctiva, except the cornea or pigmented lid; may regress or lead to carcinomas of sclera resembling papillomas with crumbly, necrotic ulcerated mass attached to the eyelid, causing irritation to eye and conjunctiva and excessive lacrimation and pus. Invasion of surrounding tissues of eye and possibly to nearby lymph nodes.

**Clinical pathology** Histology of lesion.

**Lesions** Squamous-cell carcinoma.

**Diagnostic confirmation** Biopsy and histology.

**Differential diagnosis list** Pink eye. Lymphoma of periorbital tissues.

**Treatment** Excision by cryosurgery. Radical surgery may be necessary. Immunotherapy with vaccines has been attempted.

**Control** Breeding program to increase degree of periocular pigmentation in white-faced breeds with white on their heads (Hereford, Simmental, Dutch, Normandy, Hollandens, Javanese, Mongolian, and Brahman cattle).

The tumors are uncommon in cattle younger than 5 years and are almost never seen in cattle younger than 3 years. The condemnation rate at slaughter of cattle with ocular squamous-cell carcinoma is about 30% of cases. A squamous-cell carcinoma of the anal and periareal area of a 15-year-old bull has been recorded.

### Risk Factors

The heritabilities and phenotypic and genetic correlations of eyelid and corneoscleral pigmentation and eye lesions associated with eye cancer were investigated in 2831 Herefords from 34 herds in 21 U.S. states and one Canadian province. The results indicated that periorbital pigmentation and eyelid and corneoscleral pigmentation were highly heritable and genetically correlated. These findings lead to the general conclusion that the genetic effect on pigment determines to a large extent the degree to which the eye is susceptible to an environmental carcinogenic agent such as ultraviolet light. A very high heritability estimate (*h² = 0.79*) was reported for circumocular pigmentation in 3579 Simmental cattle in Germany.

In Zimbabwe, ocular squamous-cell carcinoma was frequently observed in five breeding herds of Simmental cattle. In these herds, initial signs of the disease were evident in cattle of about 3 years of age, and gradually the prevalence increased to over 50% in animals over 7 years of age. It is suggested that because most cattle in Zimbabwe are slaughtered by 10 years of age, that more than 67% of cattle without periorbital skin pigmentation would develop the tumor. The tumors were multiple and commonly bilateral. Simmental cattle have a complete or partly white face, and the lack of facial pigmentation risks exposure to intense solar radiation when they are kept at a high altitude (1500 m) in a sunny and warm climate. The prevalence was much lower in white-faced Friesian cattle in the same light.
environment, which indicates a genetic pre-
disposition for the tumors in Simmental
cattle, separate from periocular pigmen-
tation. In Zimbabwe, the tumor is not recorded
in fully pigmented cattle breeds.

The positive association between preva-
lence of BOSCC and various measures of
solar radiation indicate a significant associ-
tion between increasing risks of developing
eye cancer and increasing levels of radiation.
Ultraviolet light is generally regarded as an
important risk factor. Most tumors are
located only in the sun-exposed mucocuta-
neous areas not protected by hair. Tumors
are predominantly localized in the third
eyelid and the lateral limbus, and tumor
growth usually starts at the outer edge, which
receives the most sunlight. Cattle exposed to
higher levels of ultraviolet radiation develop
the disease at younger ages.

Economic Importance
The disease results in serious economic con-
sequences through lessened productivity and
carcass condemnations. Commercial cattle
can be culled early without much loss,
because only the head is condemned. Pure-
bred cattle are more of a problem because of
the difficulty of deciding when euthanasia
must be the humane decision, rather than
another attempted extirpation of the eye. An
additional issue in purebred cattle is whether
the bloodline of affected cattle should be
preserved.

PATHOGENESIS
The initial lesion may be on the eyelid or any
structure in the conjunctival sac, except
the avascular cornea or pigmented eyelid.
Lesions can encroach on these tissues
from others nearby, carrying a blood supply
with them.

The lesions develop through four stages.
The first three, plaque, keratoma, and papil-
loma, are nonmalignant and have relatively
high spontaneous regression rates. The
fourth stage is the squamous-cell carcinoma,
which does not regress. The tumor is located
in the sclera adjacent to the lateral limbus, in
the membrana nictitans (third eyelid), or in
the lower eyelid (Fig. 16-11A-C). It is an
invasive tumor, metastasizing along the
draining lymphatics into cervical lymph
nodes. Primary lesions of the lids are most
likely to metastasize to these nodes.

Animals do not appear to develop resis-
tance to the cancer; only a few cows with the
disease develop measurable antibodies in
their sera. It is one of the characteristics of
this disease that the carcinomas appear to
produce immunosuppressive substances,
and removal of tumor mass reduces their
blood concentrations.

In countries and in herds where ocular
carcinoma is common, it is not unusual to
encounter lesions on the labia of the vulva,
especially if there are patches of unpig-
mented skin.

Fig. 16-11 A, Advanced plaque on the lateral limbus of the right eye from a Simmental cow.
This is a precursor to ocular squamous-cell carcinoma. B, Advanced papilloma on the third
eyelid of the right eye from a Simmental cow. This is a precursor to squamous-cell carcinoma.
Note the small amount of periocular eyelid pigmentation. C, Advanced squamous-cell
carcinoma of the right lower eyelid of a Simmental cow. The tumor mass is large enough that
metastasis to the regional lymph node was likely.
### CLINICAL FINDINGS

Typical precursor lesions are single or multiple plaques of gray-white, smooth or rough, hyperplastic to hyperkeratinized tissue anywhere in the conjunctiva (stage 1). Plaques may develop into keratoma or keratoacanthomas (stage 2) and papillomas (stage 3), which are also regarded as precursor lesions. Squamous-cell carcinomas (stage 4) may develop from any of these precursor stages, which may also regress spontaneously. Classic ocular squamous-cell carcinoma lesions resemble papillomas, with a fleshy, sometimes crumbly, often necrotic and ulcerated mass attached to the lid or the orbit by a wide base. They are visible even when the eyelids are closed, and they cause obvious irritation to the surrounding conjunctiva, resulting in increased lacrimation and sometimes in the discharge of pus. Invasion of surrounding tissues is common, but metastases to nearby lymph nodes and to visceras occur in only a few cases and then only late in the course of the disease. In general, all lesions with a dimension greater than 2 cm are cancerous (stage 4). The proportion of small precursor lesions that regress without specific treatment is up to 88%, which complicates evaluation of treatment efficacy.

The most common location for tumor development is the lateral corneoscleral junction (limbus), which usually accounts for three-fourths of all lesions. Other predilection sites are the nictating membrane (third eyelid) and middle to medial aspect of the lower eyelid. Tumors on the nictating membrane appear to grow more quickly than tumors located elsewhere. Tumors in the eyelids have a higher frequency of metastasis than tumors of the cornea or limbus; this most likely reflects total tumor volume at diagnosis, with eyelid lesions typically being more extensive when the animal is first examined for treatment.

### CLINICAL PATHOLOGY

Differentiation between carcinomas and precursor lesions is difficult clinically, and cyto logic examination or biopsy is recommended for definitive diagnoses. The cytology of squamous-cell carcinomas in domestic animals has been described.

### DIFFERENTIAL DIAGNOSIS

One of the difficulties encountered in the field is the clinical differentiation of benign precursor lesions from the malignant carcinomas; failure to do so may account for the high rates of spontaneous regression recorded, especially in Hereford cattle, where a spontaneous recovery rate of 88% has been recorded. To avoid this inaccuracy, exfoliative cytology by the examination of smears of lesions is helpful. Combined with a clinical assessment, this is the recommended method of confirming the diagnosis. Differentiation from similar lesions that are not BOSCC can only be achieved by proper laboratory examination of tissues.

BOSCC must be differentiated clinically from:

- Pinkeye and its complications, which result in excessive lacrimation and purulent material
- Lymphoma of the periorbital tissues, which usually manifests as exophthalmos

### TREATMENT

Surgical excision of small lesions with a margin of 2 to 3 mm, accompanied by cryonecrosis (two freeze–thaw cycles) of the tumor site using appropriately sized copper probes placed in liquid nitrogen, is widely practiced in cattle. Results are good to excellent in cattle with small lesions (<2 cm in dimension). Enucleation (removal of the eye) and extirpation or exenteration (removal of the eye and para-orbital tissue) is commonly performed in animals with larger lesions (>2 cm in dimension) that indicate presence of carcinoma in situ that are locally invasive. The major challenges with enucleation are intraoperative hemorrhage and postoperative infection, which occurred in 19% of 53 cattle. Radical surgery, including removal of the local lymph nodes and parts of the salivary gland, may be desirable in advanced cases of BOSCC.

Recurrence, or the development of new lesions at the same site, is common. Treatment can also be combined with immunotherapy, for example, with bacillus Calmette–Guerin (BCG) vaccine injected systemically or into the lesion, or with vaccination with BOSCC tumor material. There is a significant cell-mediated immune response in cattle with BOSCC, and it is thought that this immune process plays an important role in the rejection of the tumors. One controlled trial in cattle showed that intralesional injection of BCG vaccine can interrupt neoplastic progression and prevent malignant disease. A permanent regression after BCG vaccination can be expected in 37% of cases, recurrence at the same site in 26%, and continued growth in 37%.

A favorable response to a single injection of a saline phenol extract of fresh tumor tissue can induce a high rate of regression of ocular tumors, with a higher recovery rate after the use of 200 mg of lyophilized tumor extract compared with an injection of 100 mg. The injection may need to be repeated. Occasional tumors show enhancement of growth after vaccination, especially if it is repeated. The vaccine does not need to be autologous, and only one injection is required. A freeze-dried preparation of tumor antigen has been used successfully. In general, the use of a vaccine seems likely to provide a satisfactory method for controlling an esthetically distressing and financially important disease.

Reports on the effect of vaccination with a tumor vaccine on the vulvar form of squamous-cell carcinoma vary.

Daily peritumoral injections of BOSCC lesions up to 2.8 cm² in area with interleukin-2 for 10 days at 5000 to 1,000,000 U was effective in inducing complete tumor regression in 50% to 69% of tumors at 20 months, compared with 14% regression in control cattle injected with solvent. Lower daily IL-2 doses (<200,000 U) were similarly effective as higher doses in inducing tumor regression at 9 months, but their effectiveness was not maintained at 20 months. Interleukin-2 is thought to induce tumor regression by initially inducing edema, then angiogenesis, recruitment of monocytes, and macrophage and lymphocyte activation. However, the tumor response rate to IL-2 treatment is lower than that achieved by surgery, which remains the preferred treatment for BOSCC.

Treatment by the use of radioactive implants or topically applied radiation has also been successful, but reduced availability and concerns about the use of radioactivity in a meat-producing animal has markedly decreased the application of localized radiation therapy. Other treatments that have received favorable comment, but need to be evaluated in the light of the known natural recovery rate of the benign precursor lesions, include radiofrequency hyperthermia and combinations of the previously described procedures.

### TREATMENT AND CONTROL

#### Treatment

- Surgical excision of lesions > 2 cm in dimension (stage 4) (R-1)
- Surgical excision of lesions < 2 cm in dimension (stages 1, 2, 3, or 4) (R-1)
- Cryonecrosis (2 freeze–thaw cycles) (R-2)
- IntraleSIONAL BCG injection(s) (R-2)
- IntraleSIONAL IL-2 injections (200,000 to 2,000,000 U daily for 10 days) (R-2)
- Local radiofrequency hyperthermia (2 heating cycles) (R-2)
- Local radiation therapy (if available and permitted) (R-2)

#### Prophylaxis

Decrease exposure to ultraviolet light (usually not practical) (R-1)

Implement breeding program based on increasing periocular pigmentation (R-1)

Remove direct descendants and sires and dams of cattle diagnosed with BOSCC (R-2)

#### CONTROL

Because of the strong correlation between absence of pigmentation of the eyelids and the occurrence of the disease, and because of the high heritability of this pigmentation in Hereford and Simmental cattle, it is
suggested that a breeding program aimed at increasing the degree of pigmentation of eyelids could quickly reduce the incidence of the disease in this breed. A positive approach to the problem would be to crossbreed susceptible *B. taurus* cattle with *B. indicus* cattle, which always have pigmented eyelids and have much lower rates of eye cancer. In Ayrshires there is a corresponding predilection for squamous-cell carcinomas of the vulva, but the neoplasm does not occur on both sites in the same cow. Selection on the basis of the occurrence of lesions alone results in only limited reduction in incidence.

**FURTHER READING**

**REFERENCES**

**EQUINE OCULAR SQUAMOUS-CELL CARCINOMA**
Squamous-cell carcinoma is one of the most common neoplasms of the horse and is the most common neoplastic tumor of the eye and orbit.

Equine ocular squamous-cell carcinoma (EOSC) is associated with a number of factors, including lack of pigmentation around the eye, exposure to solar radiation, mutations in the p53 gene, and presence of equine caballus papillomavirus type 2 (EcPV-2) and bovine papillomavirus type 1 (BPV-1) DNA. EcPV-2 is also found in squamous carcinoma of the penis of horses, but not in clinically normal nictitating membrane tissue (75 horses). Although DNA of BPV-1 can be found in normal equine skin, there is increasing evidence of an etiologic link between mucocutaneous squamous-cell carcinoma (SCC) in horses and EcPV-2 infection. Approximately 25% of these tumors express cyclooxygenase-2 activity.

The reported frequency has been highest in animals lacking periocular pigmentation and is more common in Appaloosa, albino, and color-dilute horses. An increased prevalence for ocular and adnexal SCC has been reported in Belgian draft horse breeds, Appaloosas, Paint horses, Thoroughbreds, and Quarter horses. A predisposition for the development of ocular and adnexal SCC has also been reported in geldings. The risk has been higher in draft breeds than in other pigmented breeds, probably related to the large expanses of white skin on the face and around the eye of the heavy draft breeds. The overall mean age range of affected animals is 8 to 10 years. In a series of limbal neoplasms in horses admitted to the Veterinary Teaching Hospital in the Netherlands, SCC was the most predominant tumor type, and Hallinger horses accounted for 69%, whereas their occurrence in the hospital population was 5%.

In a retrospective study of 50 cases submitted to the University of Florida Veterinary Medical Teaching Hospital, the Appaloosa accounted for the majority of cases, which may be a reflection of the high level of solar radiation in southeastern United States. The average age at which the tumor was diagnosed initially was 11.8 years; males accounted for 64% and females 36% of the cases. The rate of metastasis was 18%.

In the Florida study, higher cure rates were associated with surgical excision followed by radiation therapy for a cure rate of 75%, whereas with only surgical excision the cure rate was 55%. Best results with treatment are seen when surgical intervention is early. In horses, treatment is largely surgical, but all of the immunologic techniques developed for cattle have been used, including local irradiation therapy.

The most frequent site for ocular involvement is the nictitating membrane and conjunctiva, but the eyelids and cornea are also involved.

Treatment of ocular and adnexal SCC has included various types of therapy, with and without adjuvant radiation therapy. Types of treatment without adjuvant radiation therapy include excision, cryotherapy, radiofrequency hyperthermia, immunotherapy, chemotherapy with cisplatin, and carbon dioxide laser ablation. Treatment with adjuvant radiation therapy includes use of strontium 90 (Sr), cobalt 60 (Co), gold 198, iridium 192 (Ir), cesium 137, iodine 125 (I), and radon 222 (Rn). In a series of 157 cases of ocular and adnexa SCC, those treated with adjuvant radiation therapy had a significantly lower recurrence rate compared with those treated without adjuvant radiation therapy, independent of anatomic location.

Superficial keratectomy followed by cryosurgery is a simple and effective procedure for the treatment of small-sized limbal tumors (less than 2 cm) in horses. Sophisticated equipment is not required, and the legal restrictions associated with the use of radioactive substances in many countries are not a consideration.

Prevention is through reduction of exposure to sunlight through use of fly masks and tattooing of ocular tissue.

Ocular pseudotumors have been described in horses. They are proliferative inflammatory lesions involving the eye, adnexa, or orbit, which clinically mimic true neoplasms. Cases are characterized by a uniocular, pink, proliferative limbal or perilimbal lesion. Affected horses may be from 5 to 9 years of age. Most cases occurred during the summer months and none of the affected animals had a history of trauma or recent deworming. The dorsal bulbar conjunctiva was most commonly affected, followed by the third eyelid. Lesions were relatively flat with indistinct margins or discrete and nodular. Histologically, the lesion is inflammatory and characterized by predominantly lymphocytic infiltrates. The cause is unknown, but an immune-mediated pathogenesis is suspected based on the preponderance of immunocytes consisting primarily of lymphocytes. Treatment consists of surgical excision alone, partial resection with antiinflammatory therapy, or antiinflammatory therapy alone.

**INHERITED EYE DEFECTS**
Inherited eye defects of farm animals and horses are not uncommon and typically occur in breeds that originate from a small founder base, such as, for example, with the complex ocular abnormalities of “Rocky Mountain horses” (which actually originated in the Ohio Valley of the United States) or Texel sheep. Abnormalities of the eyes include strabismus; microphthalmia; single, multiple, or complex intraocular abnormalities; cataracts; retinal abnormalities (night blindness); corneal lesions, including abnormal tissue on the surface of the cornea (dermoids) or corneal opacity; abnormal eyelid conformation (entropion); distichiasis; and absence of the nasolacrimal duct. The genetic basis for some of the more common lesions has been determined.

Inherited convergent medial strabismus with exophthalmos occurs in German Brown, Jersey, Shorthorn, Ayrshire, Bulgarian Grey, Irish Friesian, German Fleckvieh, German Black and White, and Dutch Black Pied breeds. The incidence of BCSE in German Brown cattle is 0.9% in adult cows and 0.1% in young animals. The disease appears to be inherited in an autosomal-dominant manner with incomplete penetrance, with a relative decrease in neurons in the nuclear region of the abducens nerve. This decrease in neurons induces paresis of the lateral rectus muscles and the lateral part of the retractor bulbi muscles, resulting in the clinical signs of exophthalmos and strabismus. Candidate genes for the defect are thought to be on bovine chromosomes 5 and 18.

The disease is characterized by late onset (>1 year of age) of clinical signs that are...
convergent strabismus with exophthalmos and defects in the pupil, retina, and optic disk. Susceptible cattle suffer from an inherited blindness caused by mutations in the gene responsible for the corneal lamellae.

progressive, including bilateral, symmetric, permanent rotation of the eyeballs in an anterior-medial direction and slight to severe laterodorsal exophthalmos (Fig. 16-12). Parts of the lateral rectus muscle or retrobulbar fat pad can become visible in severely affected animals. Epiptora is common in cattle with advanced BCSE. The sclera becomes darkly dark pigmented. Mildly affected animals compensate well and can be difficult to detect without close examination of the eyes, whereas more severely affected animals clearly have visual impairment up to and including blindness. There is no effective treatment.

An inherited, congenital corneal opacity occurs in Holstein cattle. The cornea is a cloudy blue color at birth, and both eyes are equally affected. Although the sight of affected animals is restricted they are not completely blind, and there are no other abnormalities of the orbit or the eyelids. Histologically there is edema and disruption of the corneal lamellae.

Lens dystrophy occurs in Brown Swiss cattle that are affected by an inherited congenital blindness. Japanese Black cattle also suffer from an inherited blindness caused by defects in the pupil, retina, and optic disk.

Congenital cataracts occur in a variety of breeds of cattle, and some have a suspected genetic component. Multiple cataracts in a herd of ayrshire cattle in Ireland were not clearly inherited, but the cause was not determined. The condition of bilateral cataracts has been observed to be an inherited defect in Romney sheep. It is inherited as an autosomal-dominant trait and can be eradicated easily by culling. Congenital cataracts in Exmoor ponies in Canada are inherited in a sex-linked fashion, with the disease being significantly more common in females.

Complete absence of the iris (aniridia) in both eyes is also recorded as an inherited defect in Belgian horses. Affected foals develop secondary cataracts at about 2 months of age. Total absence of the retina in foals has also been recorded as being inherited in a recessive manner.

Congenital stationary night blindness (CSNB) in Appaloosa horses is associated with homozygosity for the gene conferring the coat spotting pattern in horses, which itself is caused by a single incomplete dominant gene (LP). LP maps to a 6-cM region on ECAL. Expression of transient receptor potential cation channel, subfamily m, member 1 (TRPM1) in the retina of homozygous Appaloosa horses is 0.05% the level found in non-Appaloosa horses. Decreased expression of TRPM1 in the eye and the skin may alter bipolar cell signaling and melanocyte function, thus causing both CSNB and LP in horses.

Microphthalmia is reported to be an inherited defect in Texel sheep, but the incidence is low. It is a well-recognized genetic defect of Texel sheep in Europe. Following importation and “breeding up” of the breed in New Zealand in the 1990s, animals were released from quarantine for further expansion of the breed. The abnormality has occurred in a number of flocks in New Zealand, and an experimental breeding flock is maintained to study the molecular genetics. It is inherited as an autosomal-recessive trait. An outbreak in Texel sheep in New Zealand has been recorded. The optic globes are approximately one-half normal size, and the optic nerves at the chiasma are approximately one-half normal size. No other lesions are present in any organs. The retina is composed of an irregular mass attached to and continuous with the ciliary apparatus at one pole and connected to the optic nerve posteriorly by a short stalk. The morphology and morphogenesis of the defect has been followed in embryos at different ages from ewes known to be carriers of the microphthalmia factor. The primary event was abnormal development of the lens vesicle, with disintegration of the lens and subsequent overgrowth of mesenchymal tissue. The mesenchymal tissue later differentiated in various directions, whereas the epithelial structures found in the microphthalmic eyes at days 56 and 132 of gestation and in newborn lambs appeared to be remnants of the epithelial lens vesicle.

Typical colobomata, ophthalmoscopically visible defects of one or more structures of the eye, caused by an absence of tissue, have assumed a more prominent position than previously because of their high level of occurrence in Charolais cattle. The lesions are present at birth and do not progress beyond that stage. They affect vision very little, if at all. However, because they are defects, they should be named in certificates of health, but they are not usually considered as being a reason for disqualification from breeding programs. In Charolais cattle the inheritance of the defect is via an autosomal-dominant gene with complete penetrance in males and partial (52%) penetrance in females. The prevalence may be as high as 6%, and in most cases both eyes are affected. The defect is a result of incomplete closure of one of the ocular structures at or near the line of the embryonic choroidal fissure. Failure of the fissure to close represents the beginnings of the coloboma. The retina, choroid, and sclera are usually all involved.

Entropion is inherited in a number of sheep breeds, including Oxfords, Hampshires, and Suffolk. Affected lambs are not observed until about 3 weeks of age when the attention is drawn to the eyelids of the apparent conjunctivitis. A temporary blindness results, but even without treatment there is a marked improvement in the eyelids. Congenital entropion occurs in related Boer goat kids, but the mode of inheritance, if any, is unknown.

Distichiasis, in which aberrant cilia are present at the eyelid margin, appears to occur with greater frequency in Friesian horses, in which rigid cilia cause corneal irritation or corneal ulceration. Although an inherited cause is suspected, the etiology is unclear.

Ocular dermoids are recorded as genetically transmitted in Hereford cattle. They occur as multiple small masses of dystrophic skin complete with hair on the conjunctiva of both eyes of affected cattle. They can be anywhere on the cornea, on the third eyelid, or the eyelid, and they may completely replace the cornea; there may be a resulting marked dysplasia of the internal ocular structures.

Ocular dermoid cysts are single, solid, skin-like masses of tissue, adherent usually to the anterior surface of the eye, causing irritation and interfering with vision (Fig. 16-13). The eyelid, the third eyelid, and the canthus may also be involved, and the lesions may be unilateral or bilateral. When they occur at a high frequency in a population, it is likely they are inherited, as they can be in Hereford cattle. It is also recorded in foals. The defect is sometimes associated with microphthalmos. Surgical ablation is recommended.

Nasolacrimal duct fistulae, either unilateral or bilateral, occur in Brown Swiss cattle. The defect, evidenced by persistent epiphora and presence of a nasolacrimal fistula medial to the medial canthus of the eye, is inherited, although the mode of inheritance is unclear.

Combined Ocular Defects

Although the vision appears unaffected, a large number of congenital defects of the eye...
When the syndrome occurs in a large number of animals in a herd, as it does in tropical countries, it is necessary to identify the specific causative agent. R. bovis is a common cause. Affected cattle are depressed, eat little, and appear to experience high-frequency (approximately 100 to 200 horizontal oscillations/minute) nystagmus of both eyes, with the eyes moving approximately 1 mm. Nystagmus has been observed shortly after birth in some calves, but the age of onset is not accurately known. Adult animals appear to be unaffected by the nystagmus and appear to have normal vision and balance and ocular reflexes. Pendular nystagmus is not thought to affect production and should not be mistaken as indicating the presence of a serious neurologic disease.

External Ear Diseases

OTITIS EXTERNA

Otitis externa, inflammation of the skin and external auditory canal, can affect cattle of all ages, in isolated cases, an entire herd, or in entire regions.

Arthropod parasites, foreign bodies, and sporadic miscellaneous infections may cause irritation in the ear, accompanied by rubbing of the head against objects and frequent head-shaking.

In tropical and subtropical regions, parasitic otitis is more important than in other more temperate regions. The mites R. bovis and Dermanyssus avium, the tick Otobius megnini, larvae (Stephanofilaria zahaceri), free-living nematodes (Rhadinis bovis), and the blue fly (Chrysomya bezziana) are of importance in Europe, Africa, India, and America. Malassezia spp., Candida spp., Rhodotorula mucilaginosa, Aspergillus spp., and Micelis sterilia are common causes of otitis externa in cattle in Brazil.

When the syndrome occurs in a large number of animals in a herd, as it does in tropical countries, it is necessary to identify the specific causative agent. R. bovis is a common cause. Affected animals are depressed, eat little, and appear to experience...
pain when they swallow, and they shake their heads frequently. Both ears are affected in most cases, and there is a stinky, blood-stained discharge that creates a patch of alopecia below the ear. The area is painful when touched, the external meatus of the aural canal is obviously inflamed, and the parotid lymph nodes are enlarged. Extension to the middle ear is an unusual sequel. Topical treatment with ivermectin and a broad-spectrum antibiotic is effective.

Circumscribed ulcerative lesions on the ears with raised edges frequently associated with secondary bacterial or fungal infection are a common finding in cattle and buffaloes affected by buffalopox virus infection (see also “Coxpox and Bufallopox”).

**FURTHER READING**

**EAR-TIP NECROSIS**
Currently, ear-tip necrosis of pigs appears to be a more common condition.

**ETIOLOGY**
The condition may be associated with the presence of *Treponema pedis*. It can be cultured from the lesions and from the gingivae of pigs. It is anaerobic, fastidious, 4 mm to 6 mm in length, and 0.25 microns in diameter. There may be a sequence of infections when *Staphylococcus hyicus* is followed by the spirochetes and then infected with streptococci. In a recent study of putative agents, no single cause could be found, and it was suggested that the condition is multifactorial.

**EPIDEMIOLOGY**
Ear-tip necrosis is usually seen in pigs at 1 to 16 weeks of age with a peak around 8 to 10 weeks. It may also occur in older pigs, when it is usually seen at the base of the ear. Typically it may occur in only one litter of pigs, and 80% may be affected. It may be associated with mixing and moving when a lot of pigs show ear biting.

Contributing factors are thought to include poor hygiene, high humidity, low air changes, overstocking, abrasions on feeders and pen divisions, and fighting associated with moving and mixing.

**CLINICAL SIGNS**
The affected pigs appear to show little evidence of distress and often recover spontaneously, and in these cases the only evidence of the condition is a crinkled edge to the ears. When it first appears, if the grease on the ear is removed you can see a crack in the skin, which obviously then allows bacterial penetration. Some persistent lesions may enlarge and spread. Occasionally, pigs show inappetence, unthriftiness, fever, or even death, often as a result of secondary infections.

**PATHOLOGY**
The lesions are black areas of necrosis with ulcers on the tips of the ears and the caudal edge of the ears. The lesions are dry and crusty, and in some cases there may be loss of the whole ear or part of the ear. This is caused by progressive thrombi formation leading to ischemia because there is a poor collateral circulation in the ear. In cases reported in Sweden, spirochetes were observed in silver-stained histologic sections, and a spirochete isolate was obtained and identified as a yet unnamed species of the genus *Treponema* closely resembling those found in digital dermatitis in cattle. The same organism was isolated from oral samples, along with *T. socranskii*.

**DIFFERENTIAL DIAGNOSIS**
Simple ear biting is the main differential, but this usually starts at the base of the ear. Other septicemic causes of ear tissue loss, such as *H. parasuis*, *Salmonella*, or *S. suis*, may be suspected when ears are discolored, congested, or necrotic.

**TREATMENT**
Antibiotic sprays may or may not help. A recent study has suggested that vaccination for PCV-2 infections may reduce the incidence of ear-tip necrosis.

**INHERITED CROP EARS**
Inherited as a single autosomal-dominant incomplete character in Bavarian Highland cattle, the crop ear anomaly affects both ears, appears at birth, and varies from a minor trimming up to a complete deformity and reduction in size.
**Introduction**

Metabolic diseases are very important in dairy cows and pregnant ewes. In the other livestock species, metabolic diseases occur only sporadically. The high-producing dairy cow always verges on abnormal homeostasis, and the breeding and feeding of dairy cattle for high milk yields is etiologically related to metabolic disease so common in these animals. The salient features of the common metabolic diseases of farm animals are summarized in Table 17-1.

The term **production disease** includes those diseases previously known as **metabolic diseases**, such as parturient paresis (milk fever), hypokalemia, hypomagnesemia, hyperketonemia and ketosis, hyperlipemia, and other conditions that are attributable to an imbalance between the rates of input of dietary nutrients and the output of production. When the imbalance is maintained, it may lead to a change in the amount of the body’s reserves of certain metabolites and their “throughput.” This generalization applies principally to energy balance (such as ketosis and hypoglycemia), in addition to hypomagnesemia, and to a lesser extent hypocalcemia. In these diseases output is greater than input, either because of the selection of cattle that produce so heavily that no naturally occurring diet can maintain the cow in nutritional balance or because the diet contains insufficient precursors of glucose to replace the energy excreted in the milk.

**Metabolic Diseases of Ruminants**

**PERIPARTURIENT PERIOD IN CATTLE AND SHEEP**

The incidence of metabolic disease in dairy cattle increases as milk production increases and, in particular, as the rate of increase in milk production increases (called **milk yield acceleration**). In dairy cows, the total disease incidence rapidly increases in the very late periparturient period, peaks on the day of parturition, and then rapidly declines until day 7 of lactation (Fig. 17-1). This critical 7-day window starting with parturition has a tremendous influence on morbidity, lactation production, reproductive performance, and mortality.

The susceptibility of dairy cows to metabolic disease appears to be related to the extremely high turnover of water, electrolytes, and soluble organic materials during the early part of lactation. With this rapid rate of exchange of water, sodium, calcium, magnesium, chloride, and phosphate, a sudden variation in their intake because of changes in ingestion, digestion, or absorption, may cause abrupt, damaging changes in the internal environment of the animal. It is the volume of the changes in intake and secretion and the rapidity with which they can occur that affect the metabolic stability of the cow. In addition, if the continued nutritional demands of pregnancy are exacerbated by an inadequate diet in the dry period, the incidence of metabolic disease will increase. The effect of pregnancy is particularly important in ewes, especially those carrying more than one lamb.

**Transition Period in Dairy Cows**

The transition period is a crucial stage in the production cycle of the dairy cow; no other
period can affect subsequent production, health, and reproductive performance so greatly. The success of the transition period effectively determines the profitability of the cow during that lactation. Nutritional or management limitations during this time may impede the ability of the cow to reach maximal milk production. The primary challenge faced by cows is a sudden and marked increase of nutrient requirements for milk production, at a time when dry matter intake, and thus nutrient supply, lags far behind. Dry matter intake typically declines during the final week before parturition. This decline and changes in endocrine profiles contribute to elevated plasma nonesterified fatty acid (NEFA) concentrations, which have been related to the occurrence of fat-mobilization-related metabolic diseases such as fatty liver and ketosis. The magnitude of the decline in feed intake as parturition approaches may be a better indicator of metabolic health of postpartum cows than the actual level of feed intake. Diet, body-condition score, and parity influence dry matter intake and energy balance. The occurrence of diseases during the transition period results in lost milk production during the time of illness and often for the entire lactation.

A key area of the biology of transition cows is lipid metabolism. Excessive lipid metabolism from adipose tissue is linked with a higher incidence of periparturient diseases. Fatty livers were described in ketotic cows in the 1950s. Hepatic fat accumulation was then noted in normal cows during early lactation. This was followed by a description of a fat-mobilization syndrome in early lactation, in which cows mobilized body lipids from adipose tissue and deposited lipids in the liver, muscle, and other tissues. This was followed by descriptions of elevated non-esterified fatty acid concentrations during the last 7 days before calving being associated with a higher incidence of ketosis, displaced abomasum, and retained fetal membranes, but not associated with the incidence of milk fever. Understanding the metabolism of NEFA by the liver is a critical component of understanding the biology of the transition cow. Extreme rates of lipid

</table>
mobilization lead to increased uptake of NEFA by the liver and an increased rate of triglyceride accumulation in the liver. If this lipid infiltration becomes severe, the syndrome of hepatic lipodosis or fatty liver may result, which can then result in prolonged recovery from other diseases, increased incidence of other diseases, and increased susceptibility to induction of ketosis.

During the transition period, dairy cows undergo large metabolic adaptations in glucose, fatty acid, and mineral metabolism. The practical goal of nutritional management during this period is to support these metabolic adaptations. There are two different philosophic approaches for feeding transition cows in animals fed a total mixed ration. The first approach increases the energy density of the diet to “correct” for the anticipated decrease in dry matter intake in late gestation. Increasing the amount of energy supplied through dietary carbohydrate during the prepartum period results in generally positive effects on metabolism and performance of transition cows. In contrast, the second approach focuses on decreasing the energy density and increasing forage (by the daily provision of 2 to 4 kg of straw) in far-off cattle in an attempt to promote dry matter intake. Attempts to increase energy supply by feeding dietary fat sources or decrease energy expenditure by supplying specific fatty acids such as trans-10, cis-12conjugated linoleic acid to decrease milk-fat output during early lactation do not decrease the release of NEFAs from adipose tissue.

In addition to nutritional management strategies to optimize the health of the transition cow, certain feed additives are in use to reduce subclinical ketosis and reduce the incidence of displaced abomasum. Monensin is a carboxylic polyether ionophore produced by a naturally occurring strain of Streptomyces cinnamonesis. Monensin exerts its many effects by shifting the microbial populations in the rumen; this results in changes in the proportions of short-chain volatile fatty acids in the rumen, specifically increasing propionic acid and reducing the molar percentages of butyric acid and acetic acid. Increased rumen propionic acid concentrations directly lead to increased gluconeogenesis and should therefore decrease the incidence of ketosis and hyperketonemia in early lactation and improve energy balance. In Canada, monensin is approved to be administered as a controlled-release capsule (CRC) as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The monensin CRC delivers 335 mg of monensin daily for 95 days, improves energy balance, and decreases the incidence of all three energy-associated diseases of lactating dairy cows: retained placenta, displaced abomasum, and clinical ketosis. Cows treated with the monensin CRC at 3 weeks before the anticipated calving date had decreased serum NEFA and B-hydroxybutyrate (BHB) concentrations and increased serum cholesterol and urea concentrations in the week immediately preceding precalving. Monensin has no effect on serum calcium, phosphorus, or glucose concentration in the precalving period. After calving, serum concentrations of BHB and phosphorus concentrations were lower and serum concentrations of cholesterol and urea higher in monensin-treated cows. The lower NEFA values indicate less fat mobilization, and the higher cholesterol suggests greater lipoprotein export from the liver. The higher urea levels are thought to result from a protein-sparing effect in the rumen, resulting in an increased supply of amino acids in the small intestine. There was no effect of treatment on serum NEFA, glucose, or calcium concentrations in the first week postcalving. Daily monensin ingestion starting before calving therefore improves indicators of energy balance in both the immediate precalving and postcalving periods.

**Voluntary Dry Matter Intake in Periparturient Dairy Cattle**

The factors affecting voluntary dry matter intake (DMI) of lactating cattle are extremely important and have received much attention for many decades. A substantial decrease in DMI is initiated in late pregnancy and continues into early lactation, with the lowest DMI occurring on the day of calving. Postpartum DMI is considerably higher in multiparous cows compared with primiparous cows and increases after lactation in both groups, but the rate of increases varies widely. In cows given diets of constant composition, the milk yield typically peaks at 5 to 7 weeks postpartum, and the maximum intake is reached between 8 and 22 weeks after calving. The increase in DMI from week 1 postpartum to time of peak intake is affected by the diet fed during lactation and also by prepartum feeding; the latter influences the amount of fat stored and therefore the body-condition score of the animal. The normal pattern of feed intake may be severely influenced by disease states because both clinical and subclinical infections are known to substantially reduce appetite and performance.

The decrease in DMI has traditionally been attributed to physical constraints such as...
as the enlarging uterus, but this role may be overemphasized. The decrease in DMI coincides with changes in reproductive status, changes in fat mass, and metabolic changes in support of lactation. A number of metabolic signals may have a role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines and neuropeptides such as neuropeptide Y, galanin, and corticotropin-releasing factor.

**Immunosuppression During the Transition Period**

In addition to the adaptations in classical metabolism, cows during the transition period also undergo a period of reduced immunologic capacity during the periparturient period. The immune dysfunction is broad in scope, affects multiple functions of various cell types, and lasts from approximately 3 weeks before calving until approximately 3 weeks after calving. Cows during this period are more susceptible to mastitis. The etiology of periparturient immunosuppression is multifactorial and not well understood, but it seems to be related to physiologic changes associated with parturition and the initiation of lactation and to metabolic factors related to these events. Glucocorticoids are immunosuppressants, plasma cortisol concentration is increased at parturition, and endogenous glucocorticoids have been postulated to play a role in periparturient immunosuppression. Periparturient cattle have impaired expression of adhesion molecules and decreased migration capacity of blood neutrophils. Because the rapid recruitment of neutrophils into newly infected mammary tissue is the key immunologic defense against mastitis-causing pathogens in ruminants, periparturient neutrophil dysfunction may contribute to the increased susceptibility to mastitis at this time. Metabolic challenges around calving may also play a role in increased susceptibility, as non-esterified fatty acids significantly reduce the in vitro immunosuppressiveness of mononuclear cells of ewes, potentially resulting in impairment of cell-mediated and humoral immunity in sheep and cattle with ketosis.

Vitamin E is a fat-soluble membrane antioxidant that enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria. The parenteral administration of vitamin E has been investigated for the prevention of peripartum diseases such as retained placenta, metritis, and clinical mastitis. Only cows with marginal vitamin E status (serum α-tocopherol < 2.5 \( \times 10^{-3} \) mg/L) 1 week before calving will have a reduction in the risk of retained placenta following a subcutaneous injection of 3000 IU of vitamin E. In cows with an adequate serum vitamin E concentration there was no reduction, and primiparous animals were most likely to benefit from vitamin E 1 week before parturition. The associations between peripartum serum vitamin E, retinol, and β-carotene concentrations in dairy cattle and disease risk indicated that an increase in α-tocopherol of 1 µg/mL in the last week prepartum reduced the risk of retained placenta by 20%, whereas serum NEFA concentrations ≥ 0.5 mM/L tended to increase the risk of retained placenta by 80%. In the last week prepartum, a 100-ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early-lactation clinical mastitis.

**Diseases of Lactation**

Parturition is followed by the sudden onset of a profuse lactation, which, if the nutrient reserves have already been seriously depleted, may result in clinical metabolic disease. The essential metabolite that is reduced below the critical level determines the clinical syndrome that will occur. Most attention has been paid to variations in balances of calcium and inorganic phosphates relative to parturient paresis, magnesium relative to lactation tetany, and plasma glucose and ketone concentration and hepatic lipodisosis relative to ketosis, but it is probable that other imbalances are important in the production of as yet unidentified syndromes.

The vast majority of production diseases of dairy cows occur very early in lactation. At this time, the cow is producing milk at a rate that is substantially less than her maximum. In terms of rate, high- and low-milk-yielding cows are producing rather similar amounts at this time. However, in terms of acceleration, the change in milk yield per day, it is highest immediately after calving. During the succeeding period of lactation, particularly in cows on test schedules and under the strain of producing large quantities of milk, there is often variable food intake, especially when pasture is the sole source of food, and instability of the internal environment inevitably follows. The period of early lactation is an unstable one in all species. Hormonal stimulation at this stage is so strong that nutritional deficiency often does not limit milk production, and a serious drain on reserves of metabolites may occur.

**Recombinant bovine somatotrophin** (rBST, sometribove zinc) is a synthetically derived hormone that may be identical to naturally occurring bovine growth hormone, or slightly modified by the addition of extra amino acids. The product was approved in the United States in 1993, and its use began commercially in 1994 in dairy herds to increase milk production. The product is a sterile, prolonged-release injectable formulation of rBST in single-dose syringes that each contain 500 mg of sometribove zinc. The recommended dosage protocol is one syringe injected subcutaneously (SC) in the postcapular region (behind the shoulders) or in the ischiorectal fossa (depression on either side of the tailhead) every 14 days beginning during the 9th week after calving and continuing until the end of lactation. Approximately 15% of dairy herds in the United States used rBST in 2013. The product has been licensed for use in at least 20 other countries, including Argentina, Brazil, Chile, Colombia, Costa Rica, Ecuador, Egypt, Guatemala, Honduras, Jamaica, Lebanon, Mexico, Panama, Pakistan, Paraguay, Peru, Salvador, South Africa, South Korea, Uruguay, and Venezuela. In comparison, a number of countries, including Australia, Canada, Israel, Japan, New Zealand, and all European Union countries, have not approved its use.

A meta-analysis of the effects of rBST on milk production, animal health, reproductive performance, and culling was undertaken. Recombinant bovine somatotrophin was found to increase milk production by 11% in primiparous cows and 15% in multiparous cows, although there was considerable variation in the magnitude of the milk production increase between studies. Some statistically significant effects on milk composition (percentage of butterfat, protein, and lactose) were found; however, they were all very small. Treatment increased dry matter intake by an average of 1.5 kg/d during the treatment period, and dry matter intake remained elevated for the first 60 days of the subsequent lactation. Despite the increase in dry matter intake, treated animals had lower body-condition scores at the end of the treatment period, and the reduced scores persisted until the start of the subsequent lactation. Recombinant bovine somatotrophin increased the risk of clinical mastitis by approximately 25% during the treatment period, but there were insufficient data to draw firm conclusions about the effects of the drug on the prevalence of subclinical intramammary infections as assessed by somatic cell count. The increase in the incidence of clinical mastitis in cattle administered rBST appears similar to that expected from an increase in milk production alone using genetic selection and improved nutrition, milking frequency, and management practices. Use of rBST increased the risk of a cow failing to conceive by approximately 40%. For cows that did conceive, there was no effect on services per conception and only a small increase in average days open. Use of the drug had no effect on gestation length, but the information about a possible effect on twinning was equivocal. Cows treated with rBST had an estimated 55% increase in the risk of developing clinical signs of lameness. There appeared to be an increased risk of culling in multiparous cows. Use of the drug in one lactation period appeared to reduce the risk of metabolic diseases (particularly ketosis) in the early period of the subsequent lactation. It was found that the reproductive effects of the drug could be
controlled by delaying its use until the cows were confirmed pregnant.

In 1998, an expert panel appointed by the Canadian Veterinary Medical Association at the request of Health Canada found a number of legitimate animal welfare concerns associated with the use of rBST. In 1999 Health Canada announced that it would not approve the use of rBST for sale in Canada on the basis of the health and welfare of cattle. The Royal College of Physicians and Surgeons of Canada's Expert Panel on Human Safety of rBST found no biologically plausible reason for concern about human safety if rBST were to be approved for sale in Canada. In 1999 a working group from within the Scientific Committee on Animal Health and Animal Welfare of the European Commission presented a more extensive report on rBST that summarized similar results and engaged substantial discussion of animal welfare issues. It concluded that rBST should not be used in dairy cattle in Europe. In October 1999, the European Commission banned the use and marketing of rBST in the European Union as of January 1, 2000.

Relationship Between Lactational Performance and Health of Dairy Cattle

There is little evidence that high-yielding cows have increased risk of dystocia, retained placenta, metritis, and left-side displacement of the abomasum. The association between high levels of production and periparturient diseases is inconsistent; in general, high levels of management (including nutrition and housing) are usually associated with high levels of production. Although no phenotypic relationship between milk yield and the risk of ketosis and lameness has been found, selection for higher milk yield will probably increase the lactational incidence risk for both diseases. Mastitis is the only disease for which a clear relationship between increased milk yield and increased risk of infection has been found. Continued selection for high milk yield should therefore be expected to increase the incidence of clinical mastitis in dairy cattle.

However, some authors have stated that “Reviewing existing literature, even with structured literature selection, is inadequate to the task of elucidating the relationship between the lactational performance and risk of production diseases.” The most notable feature of the literature evaluation is the large variability that exists between studies. This strongly suggests that there are important factors that need to be considered before meaningful conclusions concerning the relationship between lactational performance and risk of disease can be drawn.

Breed Susceptibility

The fact that some dams are affected much more by these variations than others is probably explainable on the basis of variations in internal metabolism and degree of milk production among species and among individuals. Among groups of cows, variations in susceptibility appear to depend on either genetic or management factors. Certainly, Jersey cows are more susceptible to parturient paresis than cows of other breeds. Even within breeds, considerable variation is evident in susceptibility between families. Under these circumstances, it seems necessary to invoke genetic factors as predisposing causes for metabolic diseases.

Management Practices

The management practices of most importance are nutrition and housing. In those sections of North America where cattle are housed during the winter and in poor pasture areas, ketosis is prevalent. In the Channel Islands, local cattle are unaffected by lactation tetany, whereas the disease is prevalent in the United Kingdom. In New Zealand, metabolic diseases are complex and the incidence is high, both of which are probably related to the practice of having the cows calve in late winter when feed is poor, the practice of depending entirely on pasture for feed, and the high proportion of Jerseys in the cattle population.

Detailed knowledge of the nutrition and housing factors is essential before any reasonable scheme of prevention can be undertaken. For example, knowledge of the complex behavioral needs of the dairy cow is essential to provide adequate housing during the transition period. In North American dairy herds, the flow of cows through the transition period often necessitates many changes of pens, which are disruptive to the social organization of cow groups. Stocking rates that exceed stall and feed bunk capacity place even greater challenges on the dairy cow at this time. Current free-stall recommendations include providing 75 cm (30 in.) of bunk space for close-up and fresh cows to ensure that overcrowding does not occur, moving preparturient cows to a new pen at least 8 to 10 days ahead of the anticipated calving date or when calving is imminent, adding cows to groups on a minimum of a weekly basis (it takes up to 1.5 days for a new social order to be determined after the addition of a new animal), and keeping a clean and comfortable environment.

The diagnosis and treatment of dairy cows with periparturient diseases requires a program suited to the particular herd. Particularly in large herds, there is a need for collaboration between the veterinarian, nutritionist, manager of the herd, and animal attendants. Specific procedures should be developed for each herd based on past experience with the problems of recently calved cows, the facilities, the skills of the workers, the priorities of management, and the flow patterns of the cows in the herd. Every effort must be made to prevent periparturient diseases in the cows. In general, diseases in the early postpartum period originate in the feeding and management of the dry cow. Important principles include a protocol of grouping parturient cows according to the feeding program and handling facilities on the farm. Groups of cows can be screened for mastitis, visual evidence of illness, daily milk yield, body temperature, and urine pH, and they can be palpated for evidence of metritis. Individual cows that have been identified by a screening method must be examined individually to make a diagnosis and decide on a treatment protocol based on the particular diagnosis.

Management and environmental factors can be manipulated to ease the transition into lactation. For example, the photoperiod, defined as the duration of light exposure an animal receives within a day, can be adjusted to produce clinically significant effects on periparturient health and subsequent lactational efficiency. Increasing the frequency of milking in the immediate postpartum period also produces persistent increases in milk yield and improvements in mammary health. In both techniques, evidence is emerging to support the concept that alteration of prolactin sensitivity is the mechanism underlying health and production responses. The reader is directed to publications related to production for more information on these and related topics.

Occurrence and Incidence of Metabolic Diseases

Knowledge of the etiologic and epidemiologic factors involved will help in understanding the occurrence and incidence of the various metabolic diseases. Largely because of variations in climate, the occurrence of metabolic disease varies from season to season and from year to year. In the same manner, variations in the types of disease occur. For example, in some seasons, most cases of parturient paresis will be tetanic; in others, most cases of ketosis will be complicated by hypocalcemia. Further, the incidence of metabolic disease and the incidence of the different syndromes will vary from region to region. Ketosis may be common in areas of low rainfall and on poor pasture. Lactation tetany may be common in colder areas and where natural shelter is poor. Recognition of these factors can make it possible to devise a means whereby the incidence of the diseases can be reduced.

The metabolic diseases, because of high prevalence and high mortality rate, are of major importance in some countries, so much so that predictive systems are being set up. Rapid analysis of stored feed samples, pasture, and soil is commonly used in Europe and North America, but the interesting development has been the recognition of “production diseases” and the consequent development of metabolic profile tests, particularly in the United Kingdom and Europe.
Record Keeping
The use of reliable records to monitor the health and production of dairy cows during the transition period is essential to evaluate the efficacy of programs at the farm level. Transition cow management programs will assist in determining how well cows are prepared for milk production and good health in the coming lactation. Appropriate monitoring should focus on three areas: cows that die or are culled in early lactation, the productivity of the surviving cows in early lactation, and the rates of disease in the periparturient period.

Cows that leave the herd in the first 60 days of lactation are usually culled because of disease or injury. Removal rates and their causes can be a critical monitor of the efficacy of transition cow management programs. Measuring productivity and health of cows in early lactation involves monitoring daily milk yields, first-test mature-equivalent 305-day projected milk, milk components at first Dairy Herd Improvement Association (DHIA) test day, milk-fat percentage, ratios of test-day components, somatic cell count at first DHIA test day, and peak milk (also called summit milk). DHIA records also allow comparison of the performance of each cow in early lactation to her performance in the prior lactation. Comparisons can be made of the changes in somatic cell count between the last test of the prior lactation and the first test of the current lactation and mature-equivalent 305-day difference from the prior lactation to the first test of the current lactation.

Health and production records in dairy herds have traditionally emphasized reproductive events and administered treatments for specific diseases. The records should capture the information about the common diseases that occur in most dairy herds. The record system should be set up to do the following:

- Monitor rates of well-defined disease events as a measure of the effectiveness of health and production programs and to aid in problem solving.
- Determine the clinical efficacy of treatments by monitoring retreatment rates for specific diseases.
- Maintain an individual cow history record for cow-side use to enhance treatment decisions.
- Measure compliance and consistency of implementation of the health program being used.
- Reconcile pharmaceutical purchases with treatment protocol entries and to meet regulatory requirements on the use of pharmaceuticals in food animals.
- Determine the costs of certain disease rates over achievable targets. The costs of specific diseases are compelling to most dairy herd producers. Good records can generate an incidence rate of common diseases. These costs include the immediate cost of treatment, the cost of the veterinarian's and herdsman's time, and the cost of milk withheld from the market. For the majority of diseases of recently calved cows, the cost per disease in the United States was estimated in 2001 at approximately US$320, with a range from $150 to $450.

An adequate record system will allow producers and veterinarians to determine the differences between actual performance and benchmark performance and then determine the causes of the shortfall. The most important determinants of profitability on dairy farms are milk income and feed cost, and the difference between milk income and feed costs is the return-over-feed index (ROF). Many factors affect the ROF index. These include three-times-daily milking, component percentages in the herd milk test, milk-fat and protein percentages, use of a core lipopolysaccharide antigen mastitis vaccine, and use of monensin in the lactating-cow diet (if permitted). One of the most important factors associated with profitability is milk production. From 80% to 95% of the income on dairy farms is derived from milk sales. Thus it is critical that the producer, the veterinarian, and other advisors collaborate to plan an animal health and production program that will result in the optimum ROF.

METABOLIC PROFILE TESTING
Methods are needed to monitor the nutritional and metabolic status of dairy herds. The most valuable methods will be those that are sensitive enough to detect change before clinical or economic consequences are manifested. A major challenge in the application of metabolic profile testing is dealing with extraneous sources of variation. Successful management of extraneous variation requires sampling strategies based on animal grouping and testing of multiple animals. Larger herds are more suitable for monitoring because they allow for better design sampling strategies and spread the costs of testing across more animals. Statistical process control methods offer a unique approach to interpretation that may increase the usefulness of metabolic profiles.

The traditional approach to herd-based assessment of metabolic status (also called the Compton metabolic profile test) is based on the concept that the laboratory measurement of certain components of plasma or serum of 7 to 10 cows per subgroup will reflect the nutritional status of the subgroup, with or without the presence of clinical abnormalities. For example, a lower-than-normal mean plasma glucose concentration in a group of dairy cows in early lactation may indicate an insufficient intake of energy, which may or may not be detectable clinically. On a theoretical basis, the ability of the laboratory to make an objective assessment of the input–output (nutrient–productivity) relationships is an attractive tool for the veterinarian engaged in providing a complete health management service to a herd. The test would theoretically be able to detect the qualitative and quantitative adequacy of the diet of cows expected to produce a certain quantity of milk or return to estrus within a desirable length of time following parturition. A reliable test for the early diagnosis of nutritional deficiency or metabolic disease would therefore be a major step forward in attempting to optimize livestock production and obtain maximum yields at minimum costs.

There was considerable interest in metabolic profile testing following its earlier descriptions, which stimulated considerable field research. The results of the research have thus far indicated that the test may be useful only as an aid in the diagnosis of nutritional imbalance and production diseases. The results of metabolic profile testing are usually difficult to interpret without a careful conventional assessment of the nutritional status and reproductive performance of the herd, and it appears doubtful that such testing would reveal significant abnormalities that could not be detected using conventional clinical methods. Because of the cost of the test, the profile testing must be carefully planned with specific objectives. A regional diagnostic laboratory with automated analytical equipment should be available, and this is often a major limiting factor. The test should not be undertaken unless reference values for each laboratory measurement are available from the population within the area. The results from the groups within the herd are compared with local population means. Metabolic profiles have also been suggested as an aid in the selection of superior individuals.

The prediction of whether an individual cow is metabolically prepared to undergo a stressful lactation at a high level of production would seem to be a useful undertaking. This could be particularly important under management conditions of heavy concentrate feeding, lead feeding, zero grazing, or even indoor housing. There are no well-established, low-cost, practical protocols for conducting such profile tests.

Usefulness of Metabolic Profile Testing
Metabolic profiles in dairy cows were used initially in the United Kingdom in the 1960s. Success was limited primarily by the unjustified expectation that all biochemical concentrations in the blood of cows would reflect nutritional intake and status at all times. However, the practical value was found in the approach as an aid to nutritional management. In the 1970s the approach was reassessed and revised, culminating in a program for farmers evaluating health and productivity using metabolic profile testing as an
integral part of a health management program involving a multidisciplinary approach. The UK Dairy Herd Health and Productivity Service (DHHPS) provides the opportunity for veterinarians to lead a multidisciplinary team that can monitor health, fertility, and production and can plan, when necessary, corrective action. Effectively the approach has been to “ask the cows” what they think of their nutrition by following a set of guidelines on timing, cow selection, and the use of background information. Metabolic profiling and body-condition scoring found that at least a third of the cows sampled were mobilizing excessive fat during the transition from the dry period to early lactation. Improving both health and nutrition, before and after calving, would improve reproductive performance in many herds. The DHHPS method now utilizes a team approach involving the farmer, veterinarian, and agricultural advisor. If useful information is to be obtained, the blood-testing aspect depends critically on following a set of firm criteria for selection of small groups of typical cows within each herd; the timing of testing in relation to concentrate feeds, feed changes, and stage of lactation; and the collection of other data about the cows, such as body weight and condition, productivity, and feeding. The successful approach has been to look, following specific times of nutritional change, at metabolite levels in strictly defined small representative groups of cows within each herd in conjunction with information on body condition and weight, milk performance, and feeding. Comparison with optimum values, the degree of variation from them, and comparisons between groups within herds have allowed information about nutritional constraints on productivity to be made available to farmers more quickly and more specifically than by other means.

**Biological and Statistical Basis for Herd Testing**

The interpretation of herd-based tests for metabolic diseases is different from interpreting laboratory tests for metabolites from individual cows. Test results from individual cows are interpreted by comparing the value to a normal reference range established by the laboratory that did the testing. Normal ranges are often derived by calculating a 95% confidence interval (or a similar statistic) of test results from 100 or more clinically normal animals.

Herd test results for metabolic diseases can be interpreted as either the mean test result of the subgroup sampled or as the proportion of animals above or below a certain cut-point within the subgroup. There is a major philosophic difference and marked cost difference between the two approaches. At the moment, there does not appear to be a clear preference for either approach, and this area should be a focus of future investigation. An important difference in the approaches is that the cost of determining the mean value of a subgroup is very low if the samples from the subgroup are pooled and then analyzed. The only advantage of analyzing individual samples instead of pooled samples is that individual samples provide an estimate of the proportion of abnormal values. Whether knowing the proportion is worth the marked increased in analytical cost remains to be determined.

If a metabolite is associated with disease when it is above or below a biologic threshold (cut-point), then it should be evaluated as a proportional outcome. For example, hyperketonemia (subclinical ketosis) in dairy herds can be monitored by testing for β-hydroxybutyrate (BHB) or other ketone bodies in blood, plasma, serum, urine, or milk. Subclinical ketosis is a threshold disease, and cows are affected only when ketone concentrations are elevated. Plasma BHB concentrations above 1.0, 1.2, or 1.4 mmol/L (equivalent to 9.7, 11.7, or 14.4 mg/dL, respectively) are the most commonly used cut-points for detecting hyperketonemia (subclinical ketosis) in lactating dairy cattle. Early-lactation cows with plasma BHB concentrations above the selected cut-point have a four- to eightfold greater risk of developing displaced abomasum, a threefold greater risk of developing clinical ketosis, decreased 305-day milk production, increased severity of mastitis, a 50% increase in anestru at 60 days in milk, and a 50% decrease in pregnancy at first insemination. NEFA concentrations in plasma are an indicator of negative energy balance in prepartum cows. Elevated plasma NEFA concentration before calving (>0.4 mEq/L for cows between 2 and 14 days before the anticipated calving date) is associated with a 4-fold increased risk for displaced abomasum, a 2- to 3-fold increase in the risk of subclinical ketosis, and 1.5-fold increased risk of retained placenta after calving.

It is also necessary to determine the alarm level for the proportion of animals above or below the described cut-point. The alarm level is determined from research results or clinical experience. The suggested alarm-level proportion for plasma BHB concentration with a cut-point of 1.4 mmol/L is greater than 10%; the proportion for plasma NEFA concentration with a cut-point of 0.4 mmol/L is greater than 10%.

Herd-based testing is useful only when a sufficient number of cows within the herd are tested, which gives reasonable confidence that the results truly represent the entire population of eligible cows in the herd. In the United States, the minimum sample size for herd-based tests with proportional outcomes has been estimated as 12 cows, based on 75% confidence intervals and a general detection cut-point of greater than 10%. Cows to be sampled need to be selected from the appropriate eligible or at-risk group. Obviously, measurement of a homogeneous group requires a large herd size; to sample 12 cows consistently between day 4 and day 14 of lactation requires a milking herd of at least 428 cows, assuming equal monthly calving rates. The subgroup size recommendation of 12 cows in the United States contrasts with the subgroup size recommendation of 7 to 10 cows in the United Kingdom. The difference in recommendations has not been reconciled.

The proper use of metabolic profiles depends on the timing of blood tests, the selection of cows to be included, and the collection and use of background information about the farm, feeding and feeding system, and physical state and performance of the cows.

**Variables in Dairy-Herd Metabolic Profile Testing**

There are five main areas of interest for metabolic profile testing:

1. Energy balance
2. Protein evaluation
3. Liver function
4. Macromineral evaluation
5. Urine evaluation

In general terms, measurement of analytes in urine has been greatly underutilized in metabolic profile testing, and it is clear that current testing protocols are not economically optimized.

**Energy Balance**

Strategic use of metabolic testing to monitor transition dairy cows should focus on measuring plasma NEFA concentration in the last week prepartum and plasma/serum BHB and urine acetacetate concentration in the first and second weeks postpartum.

**Nonesterified Fatty Acids**

Plasma NEFA concentration provides the most sensitive indicator of energy balance, particularly in the last 2 weeks of gestation. Plasma NEFA concentration is useful for monitoring the energy status of dry cows in the last month of gestation, when rapid changes in energy-balance status may not be detectable from changes in body-condition score. Plasma NEFA concentrations start to increase 3 days before parturition and remain elevated for the first 9 days of lactation (Fig. 17-2). High plasma concentrations of NEFAs indicate negative energy balance, which occurs in animals that are inappetent as a result of illness.

The serum concentrations of NEFAs have been monitored in dairy cows as predictors of displaced abomasum. In cows with left-displaced abomasum (LDA), mean NEFA concentration began to diverge from the mean in cows without LDA 14 days before calving, whereas mean serum BHB concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with risk of LDA. Between day 0 and 6 days after calving, cows
with serum NEFA concentration of 0.5 mEq/L or greater were 3.6 times more likely to develop LDA after calving. In another study, cows with plasma NEFA greater than 0.3 mEq/L between 3 and 35 days before calving were twice as likely to subsequently have LDA. Strategic use of metabolic tests to monitor energy balance in prepartum dairy cows should therefore focus on measurement of plasma/serum NEFA concentration. There are three major drawbacks with this approach: the high cost of testing (US$8/test), the need to centrifuge blood to harvest serum or plasma, and the lack of a cow-side test. Until all three issues are satisfactorily resolved, plasma/serum NEFA testing will remain a research tool with minimal practical application.

**β-Hydroxybutyrate** 
Plasma/serum BHB concentrations are affected by energy and glucose balance and are a less sensitive indicator of energy balance than plasma NEFA. High plasma BHB concentrations are associated with reduced milk production, increased incidence of clinical ketosis and LDA, and reduced fertility. The gold-standard test for hyperketonemia (subclinical ketosis) is plasma/serum BHB concentration, which is more stable after collection than plasma/serum acetone or acetoacetate concentrations. Prepartum BHB concentrations are relatively stable before parturition, but increase rapidly after parturition to peak at around 9 days in milk, after which time BHB concentration gradually declines (Fig. 17-2). Subclinical ketosis may start at serum concentrations above 1.0 mmol/L. The alarm level for the proportion of cows above the cut-point of 1.0, 1.2, or 1.4 mmol/L has not been validated, but it is suggested that no more than 10% of early-lactation cows should have hyperketonemia (subclinical ketosis). In cows with serum BHB concentrations of 1.2 mmol/L or greater or 1.4 mmol/L or greater in the first week postpartum, the odds of LDA were three and four times greater, respectively, than in cows with BHB below the cut-points.2

**Glucose**  
Plasma/serum glucose concentrations are usually lower in early lactation1 and during the winter months; in early lactation, there is a heavy demand for glucose, and during the winter the energy intake is likely to be lower than necessary to meet requirements. One major cause of variation in blood glucose may be the major fluctuations in daily feed intake. Investigations of feed intake of dairy cows on commercial farms have shown that concentrate dispensers are commonly incorrectly adjusted, and errors of more than 50% in feed intake are sometimes found. In situations of marginal energy imbalance, glucose concentrations may be unreliable as an index of the adequacy of energy intake. Several factors may cause short-term changes in glucose concentration. Blood glucose may be influenced by the chemical nature of the carbohydrate and physical form of the feed and the roughage content of the feed. In addition, elevation of plasma glucose concentration has been associated with excitement and low environmental temperature.

There is some conflicting evidence about the relationship between the mean plasma glucose concentrations of a lactational group and insufficient energy intake and reproductive inefficiency. In some work, there is an expected relationship between low plasma glucose concentration and an increased incidence of ketosis. In others, the relationship is not clear; however, there was a more consistent relationship between the actual energy intake as a percentage of requirement and the plasma NEFA concentration, but this finding was not sufficiently reliable to be useful. The mean plasma glucose concentrations within 3 days before or after first service of cows that conceived on first service was higher than that of cows that returned, but the difference was only approaching significance at the 5% level, and it is doubtful whether this could be of practical value. Although plasma NEFA concentration is more sensitive than plasma glucose concentration as an indicator of energy status of the lactating cow, the excessive variability of this relationship during early lactation limits its usefulness. Plasma NEFA concentration begins to increase several weeks prepartum, peaks at parturition, and decreases gradually to normal concentrations after several weeks of lactation. Plasma glucose concentrations follow a similar pattern. The main disadvantage of using plasma glucose concentration as an index of metabolic balance is that glucose concentration is a tightly regulated variable, and marked metabolic imbalances need to be present before plasma glucose
concentration is altered. However, this means that decreased plasma/serum glucose concentrations provide an unequivocal and specific indicator of negative energy balance.

**Protein Evaluation**

Currently, there is not a single biochemical factor that accurately reflects the protein status of dairy cattle. A number of indices have therefore been monitored, including milk urea nitrogen and plasma/serum urea nitrogen, creatinine, albumin, and total protein concentrations. Of these indices, milk urea nitrogen concentration in the bulk tank provides the best global picture of protein balance in a dairy herd.

**Urea Nitrogen**

Plasma urea nitrogen and milk urea nitrogen (MUN) concentration are useful indicators of protein status, particularly when the diet contains adequate energy.

Increases in plasma urea nitrogen concentration and ammonia occur primarily as a result of inefficient nitrogen utilization. An excess of rumen degradable protein results in an increase in the concentration of rumen ammonia, which is absorbed through the rumen wall and transported to the liver, where it is converted to urea. The catabolism of body protein for gluconeogenesis can also result in the production of ammonia, which is also converted to urea in the liver. Plasma urea nitrogen concentration has therefore been the most commonly used blood constituent for monitoring protein status and intake. Values greater than 19 mg/dL suggest excessive protein intake in the diet, whereas values less than 10 mg/dL suggest inadequate protein intake in the diet.

MUN concentration can be used as a management aid to improve dairy-herd nutrition and monitor the nutritional status of lactating dairy cows. Elevated MUN concentration indicates that excess protein has been fed to the dairy cow for a given level of production. Milk samples should be submitted to an accredited diagnostic laboratory for MUN analysis. The Azotest Strip, an on-farm dipstick test, lacks accuracy and is not recommended. The MUN target concentrations for lactating dairy cows fed according to National Research Council recommendations have been evaluated. The target MUN concentrations are 8.5 to 11.5 mg/dL for most dairy herds compared with the previous target concentrations of 12 to 16 mg/dL. MUN, together with percentage milk protein, is being used increasingly as an indicator of the dietary protein–energy balance. The time of sampling can have a significant effect on MUN concentrations; the highest concentration was found to occur in the morning, and the diurnal pattern was not influenced by intrinsic factors such as parity, days postpartum or daily milk yield. MUN concentration was significantly increased after refrigeration for 1 week.

Several reviews of the literature have examined the effect of protein nutrition on reproduction in dairy cows. The reported effect of high nitrogen intake on fertility is inconsistent. Experimentally, the ingestion of a high level of degradable protein commencing 10 days before insemination in lactating dairy cows had no effect on the reproductive performance of the lactating high-yielding dairy cow. The relationship between MUN concentration and the fertility of dairy cows from 250 herds in the United Kingdom found no relationship between bulk-tank MUN concentration and fertility, or between changes in bulk-tank MUN concentrations and fertility.

A meta-analysis of the literature evaluated the associations between dietary requirements for protein for dairy cattle, the metabolism of protein in cattle, factors influencing the degradability of protein in ruminant feeds, and factors influencing MUN concentrations. There are good correlations between dietary protein intake and rumen ammonia, blood urea, and milk urea concentrations. Ryegrass clover pastures provide feed in many of the temperate dairy regions of the world, and for much of the year pasture crude protein may exceed 30%, of which a high proportion is rapidly degradable. High dietary protein intakes may have a negative effect on reproductively performance in lactating dairy cows, but the role of milk urea as a predictor of fertility needs further definition given the high conception rates in many Australian dairy herds. High intakes of dietary protein may induce adaptations in urea metabolism, and the negative relationship identified between high intakes of dietary protein and fertility for northern hemisphere dairy herds may not necessarily apply in Australian dairy herds. Because of the potential for cows to adapt to high-protein diets, the use of a single MUN determination on a herd will have limited value as an indicator of nutritional status and little value as a predictor of fertility. The differing observations between various production systems indicate the need for careful consideration in applying recommendations for dietary protein management based on milk urea concentrations. MUN determinations may, however, have value, particularly when used in conjunction with other herd and nutritional data to assess the protein nutrition of dairy herds. It is unlikely that single or even serial determinations of MUN concentration in single cows or bulk-tank milk will have a high predictive value for determining the risk of conception in the cow or herd.

**Albumin**

Plasma/serum albumin concentration is related to the protein status of the animal and whether an acute-phase reaction has been induced. Lactation stage has a substantial effect on serum albumin concentration. Animals should be grouped into dry cows, early lactation (1 to 10 weeks), and later lactation. Minimal values for dry-cow means are from 2.9 to 3.1 g/dL, from 2.7 to 2.9 g/dL for recently calved cows, and from 3.0 to 3.2 g/dL for cows in later lactation.

**Liver Function and Injury**

The presence of liver injury can be evaluated by measuring plasma/serum aspartate amino-transferase (AST), sorbitol dehydrogenase (SDH), alkaline phosphatase, and gamma-glutamyl-transferase (GGT) activities. Of these enzyme activities, the plasma/serum AST activity is the most clinically useful, with plasma AST greater than 162 U/L being indicative of hepatic lipidosis. Because increased AST activity also reflects damaged skeletal muscle, AST activity is not a specific test for liver injury in cattle at calving or for a few days after calving because of the potential for parturition-related muscle damage.

Liver function can be assessed by measuring the plasma/serum total bilirubin, cholesterol, and albumin concentrations. Serum bile acid concentration is not a useful index of liver function in cattle. Calculation of the ratio of plasma NEFA to cholesterol on a molar basis appears to provide a clinically useful index to evaluate the degree of hepatic lipidosis and the liver's ability to export mobilized peripheral fat reserves, and has been able to predict the incidence of postpartum disease. The major drawback with measuring the NEFA:cholesterol concentration is the cost, in that each analysis costs approximately US$8/test, for a total test cost of US$16. Plasma/serum albumin concentrations are decreased for the first month after calving as a result of plasma volume expansion to accommodate the nutrient flow for milk production, loss into the uterine lumen associated with uterine involution, catabolism of body protein resulting from negative energy balance, and decreased hepatic function as a result of hepatic lipidosis. The major clinical utility of plasma/serum albumin concentration is therefore in the first 4 weeks of lactation.

**Macromineral Evaluation**

Abnormalities of the blood levels of the four macrominerals, calcium, phosphorus, magnesium, and potassium, in the cow during the transition period are involved in subclinical hypocalcemia, clinical milk fever, hypomagnesemia, and acute hypokalemia.

**Calcium**

Serum calcium concentrations are tightly regulated and are not sensitive indicators of input–output balance. Measurement of plasma/serum calcium concentrations during the first 24 hours after calving, particularly in multiparous dairy cows, can provide useful insight into the effectiveness of control programs for periparturient hypocalcemia.
Phosphorus
Serum inorganic phosphate concentrations tend to fall following long-term insufficient dietary intake.

Magnesium
Serum magnesium concentrations are usually low during the winter months, and subclinical hypomagnesemia exists in many herds, especially pregnant beef cattle. This can be converted into clinical hypomagnesemia with a sudden deprivation of feed or a sudden fall in environmental temperature. Supplementation of the diet with magnesium salts is protective.

Sodium
Low serum sodium concentrations occur in early lactation in cows grazing on summer pastures without supplementation with salt. Levels down to 135 mmol/L may be associated with depraved appetite and polydipsia.

Potassium
Serum potassium concentrations have been difficult to interpret because the levels of the electrolyte in serum are not necessarily indicative of potassium deficiency. The normal serum potassium concentration is much more variable than that of sodium, and its average concentration in roughages of all kinds is nearly always in excess of requirements; any abnormalities are usually in the direction of excess.

Hematology
Hematocrit (Packed Cell Volume)
The hematocrit can be used as a general reflection of health. In most dairy herds, a low hematocrit may be a reflection of suboptimal energy and protein nutrition. Mean values of packed cell volume (PCV), hemoglobin, and serum iron are consistently higher in nonlactating cows than in lactating cows. Parasitism causing blood loss will result in a low hematocrit. The hematocrit varies with lactation stage, being highest in dry cows and lowest at peak (summit) milk. Cows should be grouped by lactation stage when evaluating hematocrit.

Urine Evaluation
Urine samples are easier to obtain than blood samples, although stimulation of the perineal area to induce urination is usually only 75% to 90% successful. Higher success rates in obtaining a urine sample are obtained in cattle that have been sitting down and that are encouraged to stand.

Urine appears to be the optimal fluid to monitor acid–base and calcium status in dairy cattle. The most accurate insight into acid–base homeostasis in healthy cattle is obtained by measuring urine net acid excretion (NAE) or net base excretion (NBE) (see Chapter 5). However, when urine pH is between 6.3 and 7.6, urine pH measured by urine dipsticks or pH papers provides an inexpensive and clinically useful insight into acid–base homeostasis in cattle. This is because the change in urine pH over this pH range accurately reflects the change in NAE or NBE. Optimum target values for urine pH to decrease the incidence of milk fever in dairy herds have not been identified, and recommendations for optimal urine pH values vary widely.5

Feeding rations with low dietary cation–anion difference (DCAD) to dairy cows for at least 2 weeks before calving decreases the incidence of periparturient hypocalcemia. The most likely reason for this effect is that ingestion of a low-DCAD diet increases calcium (Ca) flux, which in nonlactating cows is most readily detected as an increase in urinary calcium excretion. Low urine pH decreases calcium uptake from the tubular lumen into the renal epithelial cell and therefore decreases calcium absorption in the distal convoluted tubule and connecting tubule, thereby directly resulting in hypercalciuria. It remains to be determined whether laboratory measurement of urinary calcium concentration is more accurate and cost-effective than cow-side measurement of urine pH or laboratory determination of urinary strong ion difference and NBE when evaluating the effectiveness of milk-fever control programs.

Timing of Blood Tests
In Relation to Feed Changes
Because changes in the diet of ruminants cause changes in the character of rumen activity, blood samples for metabolic profile testing should not be done until 2 weeks after a major dietary change. Minor changes such as an increase in the quantity of an existing component or in access to the same ration do not require a wait of more than 7 to 10 days. Changes in forage type, such as turnout to pasture, housing, or the introduction of silage, require the full 2 weeks. The same applies for introduction of concentrates or of a new type of concentrate.

In Relation to Feeding
There can be changes in biochemical values in blood associated with feeding. These are most marked in cows receiving their entire concentrate ration at milking time. In such cases, 2 hours should be allowed to elapse after milking before blood sampling. In circumstances where the major part of the concentrate input is mixed with the forages and is available for most of each 24 hours, the timing of tests in relation to feeding is less critical. If lower-yielding midlactation cows are included (see later discussion), their results can be used as a check to see if there is an effect of feeding on the biochemical values in the blood samples. Cows should not be separated at milking time and confined for hours without access to food while waiting for blood sampling because this can also affect the results.

The available recommendations regarding the timing of blood collection relative to feeding are somewhat confusing. A common recommendation is that blood samples should be obtained 5 hours after feeding if animals are fed a fresh total mixed ration once daily. This recommendation does not seem logical in that plasma BHB concentration is increased at this time in cattle fed rations based on corn (maize) silage because of the metabolism of absorbed butyrate by ruminal epithelial cells. In most nutritional studies, blood samples are collected in a preprandial state because this is most consistent, but this will give the highest plasma NEFA concentrations over a 24-hour period. On this basis, sampling should be done in the morning immediately before or at the time of feeding of a fresh total mixed ration.

In Relation to Calving Pattern and Seasonal Feeding Changes
The cow in early lactation is the most important because what happens to her in the first few weeks after calving has the major influence on her subsequent productivity, including her future fertility efficiency. Therefore blood sampling for metabolic profiles should be carried out at the beginning of each new calving season, with the first cows checked so that the majority can benefit from the information derived. Of equal importance is the need to test as soon as possible after the introduction of a new ration, so that evaluation of the cows’ biochemistry can be made available as quickly as possible to determine what the cows, the end users, think of the ration. Therefore planning of metabolic profile tests needs to be done in advance and should take into account both expected calving pattern and feed changes. Without planning along these lines, time may be lost, and productivity with it.

Selection of Cows
Picking appropriate cows for blood sampling is very important. This is because some of the metabolites looked at, particularly those relating to energy balance, can quickly return to the optimum range as cows adapt themselves, including their productivity, to a nutritional constraint. It is possible for cows to experience a significant energy deficit in the first 2 to 3 weeks of lactation because of intake problems, lose excessive body condition, perhaps have their milk yield modified, and have their subsequent fertility efficiency suppressed, but yet still arrive at 4 weeks calved with all biochemical measurements within the optimum ranges. If blood is sampled at 4 weeks after calving or longer, a producer could see thin, underproducing cows with poor fertility but with nothing abnormal about their biochemistry. Thus the farmer would be entitled to feel the
metabolic profile test was of no value. However, if those cows had been blood sampled at 14 days calved instead of 28 days, the blood results would have been quite different and would have identified the nutritional constraint on productivity.

The guidelines for metabolic profiling of dairy cattle recommend sampling from the following groups:

- **Dry period (D):** between 7 and 10 days before anticipated date of calving
- **Early lactation (EL):** between 3 and 14 days of lactation
- **Midlactation (ML):** between 50 and 120 days of lactation.

Individual variations in biochemical values are such that single cows should not be tested. **Groups of no less than five should be sampled.** They should not be picked at random, but rather should be typical, average cows of their stage of lactation. Cows with extremes of performance—either very high or very low—should not be selected. Cows with problems should also not be included because the type of analysis carried out is not designed to clarify individual problems. It is important to make all this clear to farmers in advance because they cannot be expected to appreciate the limitations of the analyses made. Experience in the Dairy Herd Health and Productivity Service in the United Kingdom suggests that selecting cows for metabolic profiles may be best done by the veterinarian in advance of the test after looking at the calving and production records. If there is a specific concern of poor conception rate, for example, farmers may expect only cows that failed to conceive to be sampled. This tactic hardly ever delivers helpful information because any nutritional constraints have by then been compensated for, and blood biochemical values are usually within optimum ranges. The best approach may be to include such cows as the midlactation group.

**Dry-Cow Group**

Because the dry period is so important to the success of the following lactation, blood sampling to make sure nutrition is adequate is essential. However, the nature of the measurements that can be made means that primarily **cows in the last 7 to 10 days of gestation should be sampled.** Blood sampling a group of dry cows with 1 month or longer to go to calving at the same time can sometimes provide a useful within-herd comparison with respect to energy balance. Such sampling may also identify the presence of dietary protein inadequacy—specifically, rumen degradable—in the early part of the dry period.

**Early-Lactation Group**

The definition used for the early-lactation group is most critical for the reasons given in the previous paragraph. Since the original Compton metabolic profile, in which a high-yielding cow was used as the definition, the importance of this group has become increasingly apparent. The definition also has had to be changed to take into account changes in farm practice. The way cows are fed now—total mixed rations, increased out-of-parlor concentrate feeding—has reduced the time after calving by when they can adapt themselves to an unsatisfactory diet. **To be sure of detecting the presence of an energy constraint in particular, blood sampling should be carried out between 3 and 14 days calved**—at less than 3 days, the metabolic impact of hypercortisolemia associated with parturition is still present; at more than 14 days, some cows will be thin, unproductive, and subfertile but may have compensated for their nutrition and thus have normal blood metabolite values.

**Midlactation Group**

Some cows that have past the period of peak yield and so past the greatest period of potential nutritional stress should always be included. **They should be between 50 and 120 days calved** so that they are still relatively high yielding. This group provides a within-herd comparison with the early-lactation cows. Without this it is very difficult to distinguish between problems caused by constraints on intake of food or protein and energy content; to identify changes in biochemical values caused by mistiming of tests in relation to feeding or by oddities in the diet, such as silage with a high butyric acid content; and to make judgments on concentrate/forage usage within the herd.

In the DHHPS program, a majority of farms do metabolic profiles three to four times a year at critical times as a check, or “ask-the-cows-what-they-think” exercise. Thus metabolic profiles are used as part of a proactive preventive health and productivity program. Some of the larger farms may do more than 10 tests a year to cover feed changes and to check on the success of any corrective action.

In the DHHPS program, a standard DHHPS metabolic profile includes analysis of plasma for NEFA, BHB, glucose, urea nitrogen (urea N), albumin, globulin, magnesium, and inorganic phosphate. Analyses for copper and glutathione peroxidase (GSHPx) are done on approximately one-third of samples received and thyroxine T4 on even fewer. Biochemical analysis is performed using two biochemical auto-analyzers, with standard internal controls. It also employs an independent, external quality control system. Derivation of optimum metabolite values are summarized in **Table 17-2**. They are BHB less than 0.6 mmol/L in dry cows and less than 1.0 mmol/L in cows in milk; glucose greater than 3.0 mmol/L; NEFA less than 0.5 mmol/L in dry cows and less than 0.7 mmol/L in cows in milk; urea N greater than 1.7 mmol/L; albumin greater than 30 g/L; globulin less than 50 g/L; magnesium greater than 0.7 mmol/L; phosphate greater than 1.3 mmol/L; copper greater than 9.2 µmol/L; glutathione peroxidase (GSHPx) greater than 50U/g HB; and thyroxine T4 greater than 20 mmol/L.

**Energy.** The data in **Table 17-3** use only the cows fitting precisely the definitions of D, EL, and ML. The table shows that, overall, an average of 30% EL cows had metabolite results reflecting satisfactory energy status, as did 61% of ML cows and 43% of D cows. In both EL and ML groups, glucose is the metabolite most commonly outside its optimum range, followed by BHB and NEFA. The percentage of NEFA values above optimum is low in ML cows. The most common finding is high BHB and low glucose in the same cow. In tests showing most cows in an EL group having these results, there is usually one or two with high NEFAs as well. Some EL cows show only low glucose or only high NEFA. Where low glucose only predominates in EL cows, ML cows often show the same picture.

**Protein.** The plasma urea concentration results in **Table 17-3** show that the EL stage is more vulnerable to low values than later in lactation, even though the cows would have been on the same diets in virtually every case. In fact, an even greater average percentage of the blood of 1361 cows sampled between 0 and 9 days after calving over the 5 years showed low urea concentration.

The proportion of low-urea-concentration results in D cows is high (Table 17-3). In addition to the category shown of 10 days or less before calving, 4335 cows were sampled at more than 10 days

prepartum, and 22% of them had low plasma urea concentrations.

Results outside the optimum ranges for albumin (0.6%), magnesium (2.5%), phosphate (1.0%), copper (10%), and GSHPx (3%) are relatively uncommon. Thyroxine T4 analysis was carried out in 836 samples on specific request, and only 3% were below optimum.

**Background Information**

So that full value can be obtained by the farmer from the metabolic-profile approach, information about the cows and the farm should accompany the blood samples to the laboratory. This should include cow identification; last calving date for milkers/expected calving date (if pregnancy); body-weighing device/crush is required; body-condition score by a palpation method; primary milk yield; lactation number; daily milk production; lactation number; daily milk production (relative to previous lactation, or to peers) appears to provide the most sensitive and specific measure of dry matter intake and health. Milk production will provide the most practical, low-cost and immediate insight into health and production. Of all potential indices, milk production is increasing, decreases in body-tissue weight can be masked by enhanced fill of the gastrointestinal tract, so that body-weight changes do not reflect changes in adipose tissue and lean-tissue weight.

There is a strong positive relationship ($R^2 = 0.86$) between BCS and the proportion of physically dissected fat in Friesian cows. Therefore the visual or tactile (palpation) appraisal of the cow’s BCS provides a good assessment of body-fat reserves, ignoring—or minimizing the effect of—frame size and intestinal contents. Most animal and dairy scientists acknowledge the successful manipulation of BCS as an important management factor that influences or has a relationship to animal health, milk production, and reproduction in the modern dairy cow. For example, cows that lost 0.5 to 1.0 point in BCS between parturition and first service achieved a pregnancy-to-first-service rate of 53%, whereas those losing more than 1.0 point achieved a rate of 17%. A seasonal pasture-based system for Holstein-Friesian cows, it is necessary to maintain the BCS at 2.75 or greater during the breeding season. BCS is important in achieving good reproductive performance. Loss of body condition between calving and first service should be restricted to 0.5 BCS to avoid a detrimental effect on reproductive performance.

BCS is a subjective method of assessing the amount of metabolizable energy stored

in fat and muscle (body reserves) in a live animal. BCS in dairy cows is done using a variety of scales and systems. This method involves palpating the cow to assess the amount of tissue under the skin. Scoring body condition and assessing changes in the body condition of dairy cattle have become strategic tools in both farm management and research. BCS is being researched worldwide. But international sharing, comparing, and use of generated data are limited because different BCS systems are used. There is difficulty in interpreting the literature because of variability in the way authors apply scoring methods. In the United States, Canada, and Ireland, a 5-point BCS system is used for dairy cows, whereas Australia and New Zealand use 8- and 10-point scales, respectively. The following scoring method is recommended for the 0-to-5 scale. A BCS chart appears in Fig. 17-3.

### Score: 1
- **Condition:** Poor.
- **Tailhead area:** Cavity present around tailhead. No fatty tissue felt between skin and pelvis, but skin is supple.
- **Loin area:** Ends of transverse processes sharp to touch and dorsal surfaces can be easily felt. Deep depression in loin.

### Score: 2
- **Condition:** Moderate.
- **Tailhead area:** Shallow cavity lined with fatty tissue apparent at tailhead. Some fatty tissue felt under the skin. Pelvis easily felt.
- **Loin area:** Ends of transverse processes feel rounded, but dorsal surfaces felt only with pressure. Depression visible in loin.

### Score: 3
- **Condition:** Good.
- **Tailhead area:** Fatty tissue easily felt over the whole area. Skin appears smooth, but pelvis can be felt.

• Loin area: Folds of fatty tissue over transverse processes. Bone structure cannot be felt.

Relationships Among International Body-Condition Scoring Systems
The New Zealand 10-point scale was compared with the scoring systems in the United States, Ireland, and Australia by trained assessors. Cows were assessed visually in the United States, Ireland, and Australia by trained assessors. Cows were assessed by palpating key areas of the cow’s body. Significant positive linear relationships were found between the New Zealand 10-point scale and the other scoring systems in the United States and Australia; in Ireland, cows assessed by palpating key areas of the cow’s body. PARTURIENT PARESIS (MILK FEVER)

SYNOPSIS
Etiology Hypocalcemia just before, around, or after parturition.
Epidemiology Adult dairy cows in third parity and older; clinical case incidence of 4% to 9%, with low case fatality, but up to 50% of multiparous periparturient dairy cows affected subclinically. Most commonly occurs within 48 hours after calving, but also occurs several weeks before or after. Occurs in beef cattle in epidemics. Occurs in sheep and goats in epidemics, usually following stressors. Prepartum diets high in calcium.
Signs Three progressively worse stages including early signs such as restlessness, muscle fasciculation over shoulder and neck, cool skin, anorexia, rumen atony with mild bloat, and insecure gait. More advanced stages with general muscle weakness leading to sternal recumbency with head resting on the chest, mental depression, dilated pupils, weak heartbeat and pulse, increased heart rate, dry muzzle, dry feces, and hypothermia. Last stage characterized by lateral recumbency, severe obtundation, severe rumen bloat, barely audible heart, tachycardia, circulatory collapse, coma, and death.
Diagnostic confirmation Hypocalcemia and response to treatment with calcium borogluconate.
Treatment Calcium borogluconate IV, oral calcium salts.
Control Dietary management to reduce dietary potassium intake prepartum, while increasing the content of anions in the ration (low dietary cation–anion difference rations). Reducing dietary calcium content below requirements prepartum to prepare the organism for a negative calcium balance. Oral administration of calcium salts immediately before, at, and after calving. Oral or parenteral vitamin D and analogs before calving.

ETIOLOGY
A depression in the levels of ionized calcium in the extracellular space, including plasma, is the basic biochemical disturbance in milk fever. A transient period of subclinical hypocalcemia (total plasma calcium [Ca] < 2.0 mmol/L or 8 mg/dL) occurs at the onset of lactation caused by an imbalance between calcium influx to the extracellular pool from gut and bone and output in colostrum and milk. The sudden increase of Ca losses through the mammary gland at the onset of lactation presents a considerable challenge for the circuits regulating Ca homeostasis. With milk containing approximately 2 g of Ca per kg and colostrum approximately 2.3 g of Ca per kg, the production of 10 kg of milk or colostrum requires the equivalent of the entire amount of Ca available in the extracellular space of an adult cow. Calcium lost from the extracellular pool must be replaced by increasing intestinal absorption and bone resorption of calcium. Whereas the calcium requirements of a cow in late gestation are minimal at about 30 g/d, a dairy cow must mobilize an additional 30 g or more of calcium per day for milk production from parturition on. A certain degree of hypocalcemia around parturition is unavoidable and is a result of the lag time of counter-regulatory mechanisms reacting to the sudden imbalance of Ca homeostasis at the onset of lactation. Most cows adapt within 48 hours after calving by increases in plasma concentrations of parathyroid hormone (PTH) and 1,25-(OH)2D, the biologically active form of vitamin D3. The incidence of subclinical hypocalcemia, with serum Ca concentrations between 1.4 and 2.0 mmol/L (5.5 to 8.0 mg/dL) in multiparous periparturient cows has been estimated at 50%. Clinical milk fever is estimated to occur in 5% of periparturient dairy cows in the United States.

EPIDEMIOLOGY
Occurrence Cattle
The disease occurs most commonly in high-producing multiparous lactating dairy cattle. Lactating beef cows also are affected, but less commonly.
Age. Hypocalcemia at calving is age related and most marked in cows at their third to seventh parturition, although rare cases have been observed at the first and second calvings.
Breed. Field observations have for many years suggested that Jersey, Swedish Red and White, and Norwegian Red breeds develop clinical milk fever more frequently than Holstein–Friesian cows. The higher Ca concentration in milk from Jersey compared with Holstein cows has been proposed as possible explanation, although the absolute differences in Ca excreted through the mammary gland per day between breeds are negligible when considering the higher milk yield of Holstein–Friesian cows.

Differences in the number of intestinal vitamin D receptors regulating the intestinal Ca uptake have been reported in some studies. The disease in beef cattle breeds occurs either in individual cows or in herd outbreaks.

Individual Cows. Individual cows, and to some extent families of cows, are more susceptible than others; the disease tends to recur at successive parturitions. The heritability of susceptibility to milk fever and hypocalcemia has been assessed as insignificant; different studies reported heritabilities of 0%, 4%, and 12.8%. Complete milking in the first 48 hours after calving, as opposed to normal suckling by a calf, appears to be a precipitating factor. Several studies have reported that the incidence of milk fever is positively associated with the level of milk production.

Time of Occurrence. In cattle, milk fever occurs at three main stages in the lactation cycle. Most prepartum cases occur in the last few days of pregnancy and during parturition, but rare cases occur several weeks before calving. Some cases will occur a few hours before parturition or at the time of parturition when the attendant expects the cow to calve and the second stage of parturition does not occur because of uterine inertia resulting from hypocalcemia. Most cases occur within the first 48 hours after calving, and the danger period extends up to about the 10th postpartum day. Up to 20% of cases can occur subsequent to the 8th day after calving. In such cases the declines in serum Ca levels are smaller than in parturient cows. The clinical signs are also less severe, and there are fewer relapses after treatment. Occasional cases occur during mid- or even late lactation. Such cases are often recurrences of the disease in highly susceptible cows that were affected at calving. Undue fatigue and excitement may precipitate such attacks, and there is a special susceptibility at estrus. In the latter case, the depression of appetite by the elevation of blood estrogen levels may be a contributing factor.

Hypocalcemic episodes lasting 1 to 2 days may occur two or three times with a periodicity of about 9 days. Fluctuations in the intestinal absorption of Ca during this period may be the cause of Ca cycling. Subclinical hypocalcemia is of major significance because it inhibits reticulorum motility, which affects appetite, delays intestinal absorption of nutrients, and exacerbates the negative energy balance already existing in the cow in the first month of lactation.

Stressors. Feed intake depression for 48 hours contributes to the depression of serum Ca levels, and this may be of importance in the production of hypocalcemic paresis in this species at times other than in the postparturient period. Pregnant beef cattle may develop hypocalcemic paresis during the winter months when they are fed on poor-quality roughage; within a group of such cows, lower-ranked individuals of the herd may suffer selective malnutrition. The disease has also occurred in beef cows affected with diarrhea of undetermined etiology. As another explanation of the heightened susceptibility of cows at estrus, a possible depression of the degree of ionization of Ca under the influence of estrogens has been proposed. Differences in total serum Ca or plasma ionized Ca values in cows during estrus, however, are not documented.

The intravenous administration of certain aminoglycosides, especially neomycin, ellidydrostreptomycin, and gentamicin, may cause a reduction in the degree of ionization of serum calcium and a syndrome similar to milk fever. Oral dosing with zinc oxide (40 to 120 mg Zn/kg body weight [BW]) as a prophylaxis against facial eczema in ewes causes a serious drop in serum calcium levels 24 hours after treatment. Caution is recommended with the use of these drugs in parturient cows.

Sheep and Goats

In sheep, the disease commonly occurs in outbreaks in groups of ewes exposed to forced exercise, long-distance transport, sudden feed deprivation, and grazing on oxalate-containing plants or green cereal crops. These circumstances commonly precipitate outbreaks of hypocalcemic paresis in sheep; mature ewes are the most susceptible, particularly in the period from 6 weeks before to 10 weeks after lambing. Up to 25% of the flock may be affected at one time. The disease also occurs in young sheep up to about 1 year of age, especially when they graze green oats, but also when pasture is short in winter and spring, as in southeast Australia. The disease is manifested by paresis, but poor growth, lameness, and bone fragility can be detected in the rest of the flock. A sudden deprivation of feed or forced exercise of ewes can cause marked depression of the serum Ca levels. However, ewes are in a susceptible state in early lactation because they are in negative Ca balance. In late lactation, a state of positive balance is a result of a low rate of bone resorption. There is an unexplained occurrence of hypocalcemia in sheep fed on hay when they are supplemented with an energy-rich concentrate, which increases their calcium intake. Another occurrence in ewes is at the end of a drought when the pasture growth is lush and very low in Ca content. The incidence may be as high as 10% and the case-fatality rate 20% in ewe flocks in late pregnancy or early lactation.

Hypocalcemia in sheep depresses endogenous glucose production and insulin release, and in late pregnancy in combination with hyperketonemia, it facilitates the development of pregnancy toxemia.

In does, a depression in serum levels of Ca and phosphorus occurs similar to that in cows, but in ewes no such depression occurs at lambing, and the intervention of a precipitating factor appears to be necessary to reduce the serum Ca level below a critical point.

Milking goats become affected mostly during the 4- to 6-year-old age group. Cases occur before and after kidding, some later on 3 weeks after parturition. Clinical syndromes are identical to those in cows, including the two stages of ataxia and recumbency. Serum Ca levels are reduced from normal levels for parturient does.

Morbidity and Case Fatality

Clinical Hypocalcemia

Several epidemiologic studies of milk fever have reported incidence rates between 5% and 10% for clinical milk fever in cattle, calculated either as the lactational incidence or incidence per cow year. Overall clinical disease is sporadic, but on individual farms the incidence may occasionally reach 25% to 30% of high-risk cows. With early treatment mortality is low in uncomplicated cases, but incidental losses as a result of aspiration pneumonia, mastitis, and limb injuries may occur. From 75% to 85% of uncomplicated cases respond to parenteral Ca therapy alone. A proportion of these animals require more than one treatment, either because complete recovery is delayed or because relapse occurs. The remaining 15% to 25% are either complicated by other conditions or incorrectly diagnosed.

Subclinical Hypocalcemia

Subclinical hypocalcemia, defined as total plasma Ca between 1.4 and 2.0 mmol/L (5.5 and 8.0 mg/dL), is common in dairy cattle during the first few weeks of lactation. The incidence rates of subclinical postparturient hypocalcemia reported in the literature are in the range of 33% and may even increase to 50% in older cows.

Risk Factors

Animal Risk Factors

Serum Ca levels decline in all adult cows at calving as a result of the Ca loss through the mammary gland at the onset of lactation. This decline is more pronounced in some cows than in others, and it is this difference that results in the varying susceptibility of animals to parturient paresis. First-calf heifers rarely develop milk fever because
they are able to adapt more effectively to the high Ca demand at the onset of lactation. With increasing age, this adaptation process is hampered and results in moderate to severe hypocalcemia in older cows. The adaptation mechanism is directly related to the efficiency of intestinal absorption of Ca, which decreases with increasing age.

**Calcium Homeostasis.** The following three factors affect Ca homeostasis, and variations in one or more of them may contribute to the development of clinical disease in any individual:

1. Excessive loss of calcium in colostrum beyond the capacity of absorption from the intestines and mobilization from the bones to replace it. Variations in susceptibility between cows could be the result of variations in the Ca concentration in colostrum or milk and the volume of milk produced.

2. Impairment of absorption of Ca from the intestine at parturition.

3. Mobilization of Ca from storage in the skeleton may not be sufficiently rapid or efficient to maintain normal plasma Ca levels. The Ca mobilization rate is markedly reduced in cows in later pregnancy in response to the low requirements in the weeks before parturition. The lag time in reinitiating bone resorption at the moment Ca losses through the mammary gland suddenly begin contributes to the transient depression of the plasma Ca concentration. Bone resorption makes only a minor contribution to the total rate of Ca mobilization at parturition and is therefore of minor importance for the prevention of periparturient hypocalcemia. Osteoblasts are the only type of bone cell to express the 1,25-(OH) 2D receptor protein, and the decrease in the numbers of osteoblasts with increasing age could delay the ability of bone to contribute Ca to the plasma Ca pool. Bone resorption shortly before and around calving can furthermore be hampere in states of metabolic alkalosis as it occurs in cows fed a ration with high potassium content. Animals with mild to moderate forms of compensated metabolic acidosis, in contrast, have enhanced bone-resorption activity, releasing additional Ca to the extracellular pool. Preventing alkalization by avoiding excessive dietary potassium and inducing mild to moderate acidosis by adding so-called anionic salts to the diet in late gestation are common strategies for prevention of milk fever cattle (see also the discussion under “Control” in this chapter).

Historically it was proposed that failure to secrete sufficient levels of PTH or insufficient availability of 1,25-(OH) 2D was the primary defect in cows that developed milk fever. More recent research has shown that the secretion of PTH and the production of 1,25-(OH) 2D are similar in most cows with or without milk fever. However, about 20% of cows treated for parturient paresis experience relapsing episodes of hypocalcemia that require further treatment. These cows appear to be less efficient in producing adequate amounts of 1,25-(OH) 2D at the onset of lactation. Both relapsing and nonrelapsing cows develop the same degree of hypocalcemia and secondary hyperparathyroidism, but production of 1,25-(OH) 2D is about twofold greater in nonrelapsing cows than relapsing cows. Following treatment of parturient hypocalcemia with intravenous Ca salts and restoration of ruminal and intestinal motility, nonrelapsing cows establish Ca homeostasis over the next 3 to 4 days by increasing intestinal absorption of Ca, which is activated by a sufficient level of 1,25-(OH) 2D. In relapsing cows, even when rumen and intestinal motility are restored after treatment, hypocalcemia and paresis are likely to occur because of insufficient plasma 1,25-(OH) 2D. These cows may remain in this stage of prolonged hypocalcemia for several days, and only after a few days and several repeated treatments with Ca will the plasma levels of 1,25-(OH) 2D increase to an adequate level to maintain Ca homeostasis. Tissue 1,25-(OH) 2D receptor concentrations decline with age, which renders older cows less able to respond to the hormone; thus it will take longer for older cows to adapt intestinal Ca absorption mechanisms to meet lactational demands for Ca.

**Body-Condition Score.** A high BCS increases the risk of milk fever. The odds ratio of milk fever with a BCS greater than 4/5 on the first milk recording day after calving was 4.3, and cows with milk fever had a postpartum predisease body weight 12 kg higher compared with healthy cows, indicating an increased risk of milk fever as a result of higher body weight. Cows with subclinical hypocalcemia in the winter period had significantly higher mean body weight over the 60 days postpartum than normocalcemic cows, but the effect was not significant in cows calving during the summer months.

**Dietary Potassium.** The dietary potassium content of the ration fed in late gestation is a major contributing factor to the risk of periparturient hypocalcemia. Positively charged electrolytes (cations) contained in the diet and absorbed from the digestive tract tend to alkalize the organism, whereas electrolytes with a negative charge (anions) are acidifying. Studies of the 1970s furthermore demonstrated that alkalization of the organism by increasing the amount of dietary cations increased the incidence of milk fever, whereas acidification by increasing the dietary anion content reduced the milk-fever incidence, which is the basis of the so-called dietary cation–anion difference (DCAD) concept (see also the discussion under “Control” in this chapter). With potassium being the quantitatively most important cation in a standard ruminant diet, it follows that high potassium concentrations (>2% of the ingested dry matter) in the ration fed to cows in their last weeks of gestation can considerably increase the incidence of periparturient hypocalcemia.

**Dietary Magnesium.** Magnesium deficiency during late gestation is a major risk factor for periparturient hypocalcemia, and hypomagnesemia is considered to be the most common cause of milk fever occurring in midlactating dairy cows. Because magnesium is required for the release PTH from the parathyroid glands and furthermore influences the tissue sensitivity to PTH, the efficacy of PTH for the correction of hypocalcemia greatly depends on an adequate supply of magnesium.
Dietary Phosphorus. Prepartum diets high in phosphorus (P; > 80 g P/d) greatly increase the incidence of milk fever and the severity of hypocalcemia. High dietary levels of P increase the serum level of P, which is inhibitory to the renal enzymes that catalyze the conversion of vitamin D to its active form 1,25-(OH)2D. Decreased amounts of 1,25-(OH)2D will not only reduce the intestinal absorption of P, but also of Ca, and thereby predispose to periparturient hypocalcemia.

Dietary Cation–Anion Difference. Studies in the 1960s and 1970s showed that experimentally increasing the dietary cation concentration or decreasing the dietary anion concentration had an alkalinizing effect on the organisms, whereas feeding diets with a higher anion or lower cation concentration resulted in acidification. It was furthermore demonstrated that acidification achieved through feeding high-cation/low-anion diets increased the incidence of milk fever, whereas acidification by increasing the ration of anions to cations caused the milk-fever incidence to decline. Accordingly the basis of the DCAD concept is to modulate the ratio of cations to anions in the diet to reduce the risk of milk fever in cattle. The cation–anion difference of a diet is commonly given in milliequivalents (mEq) per kilogram of feed dry matter (DM; mEq/kg DM) or sometimes in mEq/100 g DM. Although several different equations have been proposed for the calculation of the DCAD, the most commonly used only considers the four quantitatively most important dietary ions: sodium (Na+), potassium (K+), chloride (Cl−), and sulfur (S2−). Other electrolytes, such as Ca, P, and magnesium, also affect the actual DCAD and thereby the effect on the acid–base status of the animal consuming the diet, and these compounds are included in some of the equations proposed in the literature to calculate the DCAD. However, because these minerals are present in relatively low amounts in the ruminant diet, their effect is considered to be minor. They are therefore commonly disregarded for practicability reasons.

The DCAD exerts a strong linear effect on the incidence of milk fever and is more important than the level of dietary Ca as a risk factor for milk fever. Prepartum diets high in cations such as potassium are associated with an increased incidence of milk fever, whereas diets high in anions, especially chloride and sulfur, result in a decrease in the incidence of the disease. Most forages, such as legumes and grasses, are high in potassium and are alkaline. The addition of anions, specifically chloride and sulfur, to the diet of dairy cows before parturition can effectively reduce the incidence of milk fever (see also the discussion under “Control” in this chapter).

Systemic acidification induced by anionic supplementation affects the function of PTH hormone, the major effect being an increased tissue response to PTH, which results in increased retention of Ca and enhanced mobilization of Ca from bone. A meta-analysis of 75 feeding trials designed to study the nutritional risk factors for milk fever in dairy cattle found that the prepartum dietary concentrations of S and dietary anion–cation balance ([Na+ + K]−[Cl− + S]) were the two nutritional factors most strongly correlated to the incidence of milk fever. Dietary S acts as a strong anion and reduces the risk of milk fever, and increasing the dietary S concentrations lowers the odds ratio of developing milk fever.

ECONOMIC IMPORTANCE

Although economic losses from milk fever have decreased considerably since the introduction of intravenous treatment with Ca salts many years ago, the disease incidences reported in recent years remain similar to values reported decades ago. The most obvious costs are associated with drugs, veterinary intervention, and losses resulting from complications in clinical cases. Costs associated with subclinical hypocalcemia are, however, considered to be far more important. Incidence rates between 3.5% and 7% for clinical disease and over 30% for subclinical hypocalcemia have been reported, and hypocalcemia is considered to be a so-called “gateway disease” that predisposes to a number of common fresh-cow disorders, such as dystocia, uterine prolapse, retained fetal membranes, mastitis, ketosis, abomasal displacement, ketosis, and immune suppression. The costs per clinical case of milk fever have been estimated at US$300, whereas subclinical cases may cost around US$125 per case, based on estimates accounting for reduced milk production and increased risk of developing periparturient disorders such as ketosis or abomasal displacement.

The literature on the effects of clinical and subclinical hypocalcemia is difficult to interpret because of the complex relationships between milk production, parity of lactation, breed of cattle, epidemiologic methods used, and management systems used, in addition to the reproducibility of the clinical observations and the accuracy of the recording systems used. In general, there is insufficient information available to document the consequences of milk fever and subclinical hypocalcemia. A summary of several consequences that have been examined follows here.

Milk Fever Relapses. Milk fever cases that need repeat treatment because of relapses increase the costs.

Downer-Cow Complications. The downer-cow syndrome associated with those milk fever cases that fail to respond to intravenous (IV) Ca treatment and remain recumbent for days before subsequently standing, those that die, or those that require destruction represents an important cause of economic loss. The literature reports incidence rates for the downer-cow syndrome ranging from 3.8% to 28.2% of milk-fever cows, with a case fatality rate of 20% to 67%.

Dystocia and Reproductive Disease. Hypocalcemia at the time of parturition can result in uterine inertia, which may cause dystocia and uterine prolapse. In general, there is an increased risk of dystocia associated with milk fever, whether the farmer or the veterinarian attends to the dystocia.

Retained Placenta. Several studies have found an increased risk of retained placenta following milk fever.

Metritis. A few studies have found an indirect relationship between milk fever and subsequent metritis.

Milk Production. There is no reliable evidence that the occurrence of milk fever or subclinical hypocalcemia in cows that recover following treatment affects milk production in the subsequent lactation. Some studies have found a limited effect, no effect, or even positive effect of milk fever on milk production.

Mastitis. Hypocalcemia not only impairs immune function but furthermore may weaken the tone of the teat sphincter, which has been proposed to facilitate intramammary infection, particularly in recumbent cows that are not milked or milked less frequently. An odds ratio of 8.1 for mastitis has been estimated, for coliform mastitis the odds ratio is estimated at 9.0, and for acute clinical mastitis a relative risk of 1.5 following milk fever has been found.

Displacement of Abomasum. Odds ratios ranging from 2.3 to 3.4 for left-side displacement of the abomasum occurring in dairy cows with hypocalcemia at parturition have been estimated.

Ketosis. Studies on the occurrence of ketosis following milk fever have found relative risks or odds ratios ranging from 1.3 to 8.9; using all the confidence intervals, the relative risks/odds ratios range from 1.1 to 15.3.

Body Weight. A temporary drop in body weight occurs in cows with milk fever, but there is no long-term effect. In cows with subclinical hypocalcemia in early lactation, there may be some weight loss compared with cows with normal levels of calcium.

Culling. There may be an increased probability of culling cows that have had milk fever because of the complications or direct or indirect consequences associated with the disease. There is some evidence of culling cows in early lactation because of milk fever, but not in late lactation.
PATHOGENESIS

Hypocalcemia

Calcium has several functions relevant for the pathophysiology of periparturient hypocalcemia, which include the following:

- **Cell membrane stability**: Calcium bound to cell membranes contributes to the maintenance of adequate membrane stability. In excitable cells the decreased availability of ionized Ca results in higher cell membrane permeability, thereby altering the resting membrane potential and making nerve cells more excitable.

- **Muscle contractility**: Calcium is required to clear the binding site for myosin on the actin molecule inside the muscle fibers. The cross-bridging between actin and myosin is the basis for the contraction of muscle fibers. Decreased availability of Ca can therefore affect muscle contractility.

- **Release of acetylcholine**: Calcium is required for the neuronal release of the neurotransmitter acetylcholine into the synaptic cleft of the neuromuscular junctions. Calcium depletion can thus hamper the signal transmission at the level of the neuromuscular endplate.

Whereas decreased membrane stability and ensuing increased excitability are the probable underlying cause of hypocalcemic tetany of monogastric species and the muscle twitching observed in the early stages of milk fever in cattle, disturbed muscle fiber contractility and neurotransmitter release are considered the basis of the flaccid paresis observed in advanced stages of milk fever in ruminants.

The plasma Ca concentration is normally maintained between 2.1 and 2.6 mmol/L (8.4 to 10.4 mg/dL). Almost all multiparous dairy cows will experience at least transient and subclinical hypocalcemia, less than 1.8 mmol/L (7.5 mg/dL), within 24 hours after calving. In some cows, hypocalcemia is more pronounced, causing neuromuscular dysfunction resulting in clinical milk fever. Without treatment, levels may continue to decline to values as low as or even below 0.5 mmol/L (2 mg/dL), which is usually incompatible with life.

Hypocalcemia is the cause of the signs of typical milk fever. Atony of skeletal muscle and plain muscle are well-known physiologic effects of hypocalcemia in ruminants.

**Experimental Hypocalcemia**

Hypocalcemia can be induced experimentally by administering Na₂-EDTA intravenously, which results in the complex binding or chelation of ionized Ca. The IV infusion of Na₂-EDTA into cows over a period of 4 to 8 hours results in severe hypocalcemia and paresis and has been used extensively as a model for the reproduction of the disease. A standardized flow rate of 1.2 mL/kg per hour of a 5% solution of Na₂-EDTA until recumbency results in changes in plasma ionized Ca, total Ca, inorganic phosphate (Pi), and magnesium comparable to what is observed in spontaneous cases of milk fever. Induced hypocalcemia results in depression of the frequency and amplitude of rumen contractions as early as 1.0 mmol/L of ionized serum Ca, well before any clinical signs of hypocalemia are detectable and while feeding behavior and rumination are still normal. The induction of subclinical hypocalcemia in cows results in a linear decrease in feed intake and chewing activity as the plasma ionized calcium decreases. Feed intake depression was observed with ionized Ca concentrations below 0.9 mmol/L and before other signs commonly associated with hypocalemia were recorded. Feed intake approached zero when ionized Ca concentrations declined to 0.6 mmol/L. This suggests that hypocalcemia may contribute to the reduction in feed intake prepartum and depresses the rumination process, ultimately leading to anorexia. Experimental hypocalcemia in cattle furthermore resulted in a marked reduction in cardiac stroke volume, a 50% reduction in arterial blood pressure, and a significant reduction in ruminal and abomasal tone and motility.

In experimental hypocalcemia in sheep, blood flow is reduced by about 60% to all tissues except the kidney, heart, lung, and bladder, in which the reduction is not as high. During periods of prolonged hypocalcemia in cows and ewes, blood flow to skeletal muscles and the alimentary tract may be reduced to 60% to 70% of normal for a long period, which may present a predisposing factor for the downer-cow syndrome. Serum Ca and Pi levels are significantly lower in clinical cases than in comparable normal cows, and there is some relationship between the severity of the signs and the degree of biochemical change.

Signs of hypocalcemic tetany, presumably attributable the increased membrane instability, commonly recognized in nonruminant species are observed in the initial stages of milk fever in cattle:

- Nervousness and early excitement
- Muscle twitching
- Tetany, particularly of the hindlimbs
- Hypersensitivity and convulsive movements of the head and limbs

There are additional signs in the experimental disease, such as excessive salivation, excessive lip and tongue actions, and tail lifting. The serum muscle enzyme levels of creatine phosphokinase (CPK) and aminotransferase (AST) increase as a result of muscle injury associated with prolonged recumbency. Blood glucose levels increase, and serum Pi and potassium levels decrease.

The prolonged infusion of Na₂-EDTA in sheep over 18 hours at a rate to induce hypocalcemia and maintain recumbency resulted in prolonged periods of recumbency ranging from 36 to 64 hours before the animals were able to stand. There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in PCVs, suggesting that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia. The activity of AST and CPK, the PCVs, and white blood cell (WBC) counts were elevated 24 hours later.

**Hypomagnesemia**

Hypomagnesemia is recognized as an importing contributing factor to periparturient hypocalcemia and has been proposed to be the major risk factor for milk fever occurring in cattle in mid- to late lactation. The two mechanisms through which Mg deficiency may predispose to hypocalcemia are an impaired release of PTH in response to hypocalcemia and decreased tissue sensitivity to PTH in hypomagnesemic states. Hypomagnesemia can therefore predispose to clinical or subclinical milk fever by blunting the main counter-regulatory mechanism of hypocalcemia.

**Hypophosphatemia**

Low serum Pi concentrations are commonly observed in milk-fever cows, but also in healthy dairy cows, around parturition. Although the clinical relevance of hypophosphatemia in recumbent cattle remains uncertain, empirical associations between hypophosphatemia and recumbency have been established. Anecdotal reports from field veterinarians suggest that the numbers of recumbent periparturient dairy cows not responding to standard therapy with intravenous Ca salts and showing pronounced hypophosphatemia have increased in recent years. To date, however, there is no unequivocal evidence corroborating the hypothesis that hypophosphatemia plays a role in periparturient recumbency or confirming the treatment efficacy of oral or parenteral Pi supplementation to recumbent cattle.

**CLINICAL FINDINGS**

**Cattle**

Three stages of milk fever in cattle are commonly recognized and described.

**Stage 1**

In the first stage, the cow is still standing. This is also the brief stage of nervousness, excitement, and tetany with hypersensitivity and muscle tremor of the head and limbs. The animal is disinclined to move and often has a decreased or no feed intake. There may be a slight shaking of the head, protrusion of the tongue, and grinding of the teeth. The rectal temperature is usually normal to slightly above normal; the skin may feel cool to the touch. The animal appears ataxic, with a stiff and insecure gait, and falls easily. Close examination reveals agalactia, rumen stasis, and scant feces. Heart rate and respirations may be within normal limits or slightly elevated.
Stage 2
The second stage is characterized by sternal recumbency with depressed consciousness; the cow has a drowsy appearance in sternal recumbency, usually with a lateral kink in the neck or the head turned into the flank (Fig. 17-4). When approached, some of these cows will open their mouths, extend the head and neck, and protrude their tongues, which may be an expression of apprehension and fear in an animal unable to stand. The tetany of the limbs present in the first stage is not present, and the cow is unable to stand. The muzzle is dry, the skin and extremities cool, and the rectal temperature subnormal (36 to 38°C, 97 to 101°F). There is a marked decrease in the absolute intensity of the heart sounds, whereas the heart rate is increased (about 80 bpm). The arterial pulse is weak and the venous pressure is also low, making it difficult to raise the jugular veins. The respirations are not markedly affected, although a mild forced expiratory grunt or groan is sometimes audible. Ruminal stasis and secondary bloat are common, and constipation sometimes audible. The eyes are usually dry and staring. The pupillary light reflex is incomplete or absent, and the diameter of the pupil varies from normal to maximum dilatation. A detailed examination of the pupils of cows with par -turient paresis found that the mean size of the pupils was not significantly different from one another. Rather, disparity of the size of the pupils was common. In cows that develop hypocalcemia a few hours before or at the time of parturition, the second stage of parturition may be delayed. Vaginal examination usually reveals a fully dilated cervix and normal presentation of the fetus. The cow may be in any stage of milk fever, and administration of Ca-salts IV will usually result in a rapid beneficial response and normal parturition.

Prolapse of the uterus is a common complication of milk fever, and often the Ca levels are lower than in parturient cows without uterine prolapse. Thus it is standard practice to treat cases of uterine prolapse with IV calcium salts.

Stage 3
The third stage is characterized by a severely obtunded or even comatose cow in lateral recumbency. There is complete flaccidity on passive movement, and the cow cannot assume sternal recumbency on its own. In general, the depression of temperature and the cardiovascular system are more marked. The heart sounds are almost inaudible, and the rate is increased up to 120 bpm; the pulse is almost impalpable, and it may be impossible to raise the jugular veins. Boat is common because of prolonged rumen stasis and lateral recumbency. Without treatment, a few animals remain unchanged for several hours, but most become progressively worse during a period of several hours and die quietly from shock in a state of complete collapse.

**Concurrent Hypomagnesemia.** Mild to moderate tetany and hyperesthesia persisting beyond the first stage suggests a concurrent hypomagnesemia. There is excitement and fibrillary twitching of the eyelids, and tetanic convulsions are readily precipitated by sound or touch. Trismus may be present. The heart and respiratory rates are increased, and the heart sounds are much louder than normal. Without treatment, death occurs during a convulsion.

**Sheep and Goats**
The disease in pastured ewes is similar to that in cattle. The early signs include a stilty, proppy gait and tremor of the shoulder muscles. Recumbency follows, sometimes with tetany of the limbs, but the proportion of ewes with hypocalcemia that are recumbent in the early stages is much less than in cattle. A similar generalization applies to female goats. The characteristic posture is sternal recumbency, with the legs under the body or stretched out behind. The head is rested on the ground, and there may be an accumulation of mucus exudate in the nostrils. The venous blood pressure is low and the pulse impalpable. Mental depression is evidenced by a drowsy appearance and depression of the corneal reflex. There is loss of the anal reflex, constipation, tachycardia, hypersensitivity, ruminal stasis and tympany, salivation and tachypnea. Response to parenteral treatment with Ca salts is rapid; the ewe is normal 30 minutes after an SC injection. Death often occurs within 6 to 12 hours if treatment is not administered. The syndrome is usually more severe in pregnant than in lactating ewes, possibly because of the simultaneous occurrence of pregnancy toxemia or hypomagnesemia. Fat late-pregnant ewes on high-grain diets indoors or in feedlots show a similar syndrome accompanied by prolapses of the vagina and intestine.

**CLINICAL PATHOLOGY**
Total serum Ca levels are reduced to below 2.0 mmol/L (8 mg/dL), usually to below 1.2 mmol/L (5 mg/dL), and sometimes to as low as 0.5 mmol/L (2 mg/dL). The reduction is usually, but not always, proportional to the severity of the clinical syndrome. Average figures for total serum Ca levels in the three species are as follows: cows, 1.30 ± 0.30 mmol/L (5.2 ± 1.2 mg/dL); ewes, 1.15 ± 0.37 mmol/L (4.6 ± 1.5 mg/dL); goat does, 0.94 ± 0.15 mmol/L (3.8 ± 0.6 mg/dL).

Although the concentration of ionized Ca, which is the biologically active fraction of the total Ca pool, is the factor determining the presence and severity of clinical signs in hypocalcemic animals, the total serum Ca concentration is commonly used for convenience. Measurement of ionized Ca concentration requires the use of ion-selective electrodes, which have become much more accessible in recent decades. Nonetheless, the association between ionized and total Ca in serum is tight, with excellent correlation between the two, which is why total Ca concentration in serum is considered clinically useful and sufficiently accurate in practice. Between 42% and 48% of the total Ca content in the extracellular space is available as biologically active ionized Ca. A decrease in serum albumin or acidemia tends to increase the ionized Ca fraction, whereas alkalalemia or an increase in serum albumin tends to decrease the proportion of ionized Ca.

Equine, bovine, and ovine blood may be
stored for up to 48 hours without any clinically relevant alteration of blood Ca ion concentration.

Levels of ionized Ca in the venous whole blood of cows are as follows: normal, 1.06 to 1.26 mmol/L (4.3 to 5.1 mg/dL); slight hypocalcemia, 1.05 to 0.80 mmol/L (4.2 to 3.2 mg/dL); moderate, 0.79 to 0.50 mmol/L (3.2 to 2.0 mg/dL); severe hypocalcemia, less than 0.50 mmol/L (<2.0 mg/dL). Total serum Ca levels are reduced below normal in all cows at calving, whether they have milk fever or not, but not in ewes.

Serum magnesium levels are usually moderately elevated to 1.65 to 2.06 mmol/L (4 to 5 mg/dL), but in some areas low levels may be encountered, especially in cows at pasture.

Serum inorganic phosphorus (Pi) levels are usually depressed to 0.48 to 0.97 mmol/L (1.5 to 3.0 mg/dL). Blood glucose levels are usually normal, although they may be depressed if ketosis occurs concurrently. Higher-than-normal blood glucose levels are likely to occur in cases of long duration and are presumably because Ca is required for the release of insulin from the pancreas.

Serum Muscle Enzyme Activity
Prolonged recumbency results in ischemic muscle trauma and necrosis and increases in the serum muscle enzyme activity of creatine kinase (CK) and aspartate aminotransferase (AST). During prolonged recumbency following treatment for milk fever, the levels of CK will remain elevated if muscle trauma is progressive in animals that are not rolled from side to side every few hours to reduce the effects of compression on the large muscle groups of the pelvic limbs (see also the discussion under “Downer-Cow Syndrome” in this chapter).

Hemogram
Changes in the leukocyte count include eosinopenia, neutrophilia, and lymphopenia suggestive of adrenal cortical hyperactivity, but similar changes occur at calving in cows that do not develop parturient paresis. High plasma cortisol levels and PCVs occur in cows with milk fever and are higher still in cows that do not respond to treatment. They are expressions of stress and dehydration. Clinicopathological findings in the other species are not described in detail except with regard to depression of total serum calcium levels.

Necropsy Findings
There are no gross or histologic changes unless concurrent disease is present.

Differential Diagnosis
A diagnosis of milk fever is based on the occurrence of paresis and depression of consciousness in animals following parturition. The diagnosis is supported by a favorable response to treatment with parenteral injections of calcium solutions and by biochemical examination of the blood. In ewes, the history usually contains some reference to recent physical stress, and the disease is more common in the period preceding lambing.

There are several diseases that cause recumbency in cows in the immediate postpartum period, and their differentiation is summarized in Table 17-5.

Several diseases that occur at the time of parturition must be differentiated from milk fever in cattle. These are grouped here according to the following categories:
- Other metabolic diseases
- Diseases associated with toxemia and shock
- Injuries to the pelvis and pelvic limbs
- Degenerative myopathy
- Downer-cow syndrome

Metabolic Diseases
Hypomagnesemia may occur as the sole cause of recumbency; it may accompany a primary hypocalcemia or result in secondary hypocalcemia so that the case presented is one of parturient paresis complicated by lactation tetany. Hyperesthesia, tetany, tachycardia, and convulsions are common instead of the typical findings of depression and paresis in milk fever.

Hypophosphatemia, which commonly accompanies milk fever, is suggested as a cause of continued recumbency in cows after partial response to Ca therapy; serum Pi levels are low and return to normal if the cow stands or following treatment with calcium salts. The role of hypophosphatemia in the etiology of periparturient recumbency in cattle is under contentious debate. Although there is no unequivocal evidence available supporting the role of P in the etiology of recumbency in cattle, cows not responding to IV Ca were found to have lower serum P levels.

Severe hypokalemia (<2.5 mmol/L) in dairy cows is characterized by extreme weakness or recumbency, especially after treatment for ketosis with isoulnepredone. Clinical signs tend to resemble botulism rather than hypocalcemia, with flaccid paralysis of the tongue and masticatory muscles and the head resting on the ground rather than on the chest of the cow. The case-fatality rate is high in spite of therapy with potassium. Hypokalemic myopathy is present at necropsy.

Ketosis may complicate milk fever, in which case the animal responds to Ca therapy by standing but continues to manifest the clinical signs of ketosis, including in some cases the nervous signs of licking, circling, and abnormal voice.

Diseases Associated With Toxemia and Shock
During the immediate postparturient period, several diseases occur commonly and are characterized by toxemia.

Acute or peracute coliform mastitis is characterized by one or several obviously enlarged and inflamed mammary glands with watery and serouslike secretions that may be overlooked if the cow is recumbent. Other signs include fever in early stages that may be followed by hypothermia in advanced stages of toxemia or septicemia, tachycardia, dehydration, depression and weakness up to the point of recumbency, ruminal stasis, and frequently also watery diarrhea.

Aspiration pneumonia secondary to regurgitation and aspiration of rumen contents is a complication of third-stage milk fever, or accidental aspiration or fluid administration into the trachea of periparturient cattle that were meant to be drenched. Fever, dyspnea, inspiratory grunt, severe depression, and anxiety are common. Auscultation of the lungs reveals the presence of abnormal lung sounds. Aspiration pneumonia should be suspected if the animal has been lying on its side, especially if there is evidence of regurgitation of ruminal contents from the nostrils, no matter how small the amount, or if there is a history of the animal having been drenched. Abnormal auscultatory findings may not be detectable until the second day. Early diagnosis is imperative if the animal is to be saved, and the mortality rate is always high.

Acute diffuse peritonitis resulting from traumatic perforation of the abomasum or uterus is characterized by severe depression, tachycardia, dehydration, ruminal stasis, fever, weakness and recumbency, grunting or groaning with respiration, and possibly splashing sounds on ballottement of the abdomen.

Carbohydrate engorgement (grain overload) results in depression, dehydration, tachycardia, hypothermia, diarrhea, and weakness up to the point of recumbency. The rumen is atonic and mildly to moderately bloated. The rumen content is watery, and the fiber matt is absent. A positive steelband sound and splashing sounds may be audible over the rumen on auscultation and percussion of the left flank. Examination of the rumen fluid will reveal a sour smell with low pH (<5.0). Microscopic examination of a smear will reveal absence of living protozoa and a predominance of gram-positive microorganisms if a stain is performed.

Toxemic septic metritis occurs most commonly within a few days after parturition and is characterized by depression, anorexia, fever, tachycardia (100 to 120 bpm), ruminal stasis, and presence of foul-smelling uterine discharge found on vaginal examination. The fetal placenta may be retained. Some affected cows are weak and prefer recumbency, which resembles milk fever.

Prolapse and rupture of the uterus cause varying degrees of shock, with tachycardia, hypothermia and cool extremities, weakness and recumbency, and rapid death. A history of difficult parturition or assisted dystocia...

Injuries to the Pelvis and Pelvic Limbs

Injuries to the pelvis and pelvic limbs are common at parturition because of the marked relaxation of the ligaments of the pelvic girdle. Seven types of leg abnormalities have been described in this group at an incidence level of 8.5% in 400 consecutive cases of parturient paresis. The described abnormalities include radial paralysis, hip dislocation, and rupture of gastrocnemius muscle. In most instances the affected animals are down and unable to stand, but they mentally alert; eat, drink, urinate, and defecate normally; have a normal temperature and heart rate; and make strong efforts to stand, particularly with the forelimbs.

Maternal obstetric paralysis is the most common injury. Although this occurs most frequently in heifers after a difficult parturition, it may also occur in adult animals following an easy birth and occasionally before parturition, especially in cows in poor body condition. The mildest form is evidenced by a frequent kicking movement of a hindleg, as though something was stuck between the claws. All degrees of severity—from the mild kicking through knuckling and weakness of one or both hindlegs, to complete inability to rise—may occur, but sensation in the affected limb is usually normal. There is traumatic injury to the pelvic nerves during passage of the calf. There are often gross hemorrhages, both deep and superficial, and histopathological degeneration of the sciatic nerves. In individual animals, injury to the obturator nerves is common and results in defective adduction of the hindlimbs. The position of the hindlimbs may be normal, but in severe cases, especially those with extensive hematoma along the sciatic nerve trunk, the leg may be held extended with the toe reaching the elbow as in a dislocation of the hip; marked relaxation of the ligaments of the pelvic limbs. Additional injuries causing recumbency near parturition include those associated with degenerative myopathy, dislocation of the hip, and ventral hernia.

Dislocation of the coxofemoral joint can cause recumbency and inability to stand in some cows, whereas others can stand and move around. Recumbent cows are usually in sternal recumbency, and the affected limb is abducted excessively. In standing cows, the affected limb is usually extended, often difficult to flex, and often rotated about its long axis. The diagnostic criteria are as follows:

- Sudden onset of lameness with the affected limb extended and possibly rotated
- Displacement of the greater trochanter of the femur from its normal position relative to the ischiatric tuber and coxal tuber of the pelvis (compare left and right rear limb)
- Ability to abduct the limb manually beyond its normal range
- Crepitus in the hip on abduction and rotation of the limb
- Ability to palpate the femoral head per rectum or per vagina against the cranial border of the ilium or pubis in cases of cranioventral dislocation, or in the obturator foramen in cases of caudoventral dislocation

Manual replacement by closed reduction is successful in 80% of cases of craniodorsal dislocation and in 65% of cases of caudodorsal dislocation; relapses are, however, common. The ability to stand before reduction is the most useful prognostic aid.

Degenerative Myopathy (Ischemic Muscle Necrosis)

Degenerative myopathy, affecting primarily the large muscles of the thighs, occurs commonly in cattle that have been recumbent for more than several hours. At necropsy, large masses of pale muscle are present, surrounded by muscle of normal color. Clinically, it is indistinguishable from sciatic nerve paralysis. Markedly increased serum activities of CK occur in cows recumbent for several hours following the initial episode of milk fever as a result of ischemic necrosis. Persistent elevation of CK activity indicates progressive ischemic muscle necrosis as a result of continued compression of the large muscle masses of the pelvic limbs. Rupture of the gastrocnemius muscle or separation of its tendon from either the muscle or the tuber calcis may also cause myopathy.

Downer-Cow Syndrome

Downer-cow syndrome is a common sequel to milk fever in which postparturient cows that may initially have been hypocalcemic remain recumbent for unknown reason after repeated intravenous treatment with Ca salts. Following treatment, most of the clinical findings associated with milk fever resolve, but the animal remains unable to stand. Clinically, the animal may be alert with normal or slightly decreased appetite and will commonly recover and stand normally within several hours or a few days. The animal’s vital signs are within the normal range, and its alimentary tract function is normal. However, some affected animals are anorexic, may not drink, exhibit bizarre movements of lying in lateral recumbency, dorsally extend the head and neck frequently, moan and groan frequently, assume a frog-legged posture with the pelvic limbs, and crawl or creep around the stall; these animals may die or are euthanized for humane reasons within a few days.

The diagnostic dilemma with these cows is that, at least initially, they resemble cows with milk fever, and whether or not to treat them with additional amounts of calcium salts is questionable.

Nonparturient Hypocalcemia

Paresis with mental depression and associated with low total serum Ca levels can occur in cows at times other than at parturition. The cause is largely unexplained, but hypomagnesemia has been proposed as a major risk factor for this atypical form of clinical milk fever in cattle. Hypocalcemia may also occur after gorging on grain and may be a significant factor in particular cases. Sudden rumen stasis as a result of traumatic reticulitis may rarely cause hypocalcemic paresis. Diarrhea, particularly when cattle or sheep are placed on new lush pasture, may also precipitate an attack. Access to plants rich in oxalates may have a similar effect, particularly if the animals are unaccustomed to the plants. Affected animals respond well to Ca therapy, but relapse is likely unless the primary cause is corrected. The differential diagnosis of diseases of nonparturient cows manifested principally by recumbency is also summarized in Table 17-5.

Hypocalcemic Paresis in Sheep and Goats

Hypocalcemia in sheep must be differentiated from pregnancy toxemia, in which the course is much longer, the signs indicate cerebral involvement, and the disease is restricted to pregnant ewes. There is no response to Ca therapy, and a positive test for ketonuria is almost diagnostic of pregnancy toxemia. At parturition, goats are susceptible to enterotoxemia and hypoglycemia (rarely), both of which present clinical signs similar to parturient paresis.

Hypocalcemia in Sows

Hypocalcemia is rare in sows. The disease must be differentiated from the mastitis, metritis, and agalactia complex, which is characterized by fever, agalactia, anorexia, toxemia, and enlarged and inflamed mammary glands.

Treatment

Every effort must be made to treat affected cows as soon as possible after clinical signs are obvious. Treatment during the first stage of the disease, before the cow is recumbent, is the ideal situation. The longer the interval between the time the cow first becomes recumbent and treatment, the greater the incidence of downer-cow syndrome as a result of ischemic muscle necrosis from prolonged recumbency. Complications of milk fever occur when cows have been in sternal recumbency for more than 4 hours. Farmers must be educated to appreciate the importance of early treatment. Cows found in lateral recumbency (third stage) should be placed in sternal recumbency until treatment is available. This will facilitate eructation and reduce the risk of aspiration if the cow regurgitates. Cows that have difficulty finding solid, nonslip footing beneath them will often not try to stand and may develop ischemic myonecrosis. Avoidance of this complication necessitates the placement of rubber or other mats under the cow or
transportation of the cow to a piece of pasture with a dense sward on it.

**Standard Treatment**

IV with solutions containing Ca as Ca-glucuronate, Ca-borogluconate, and—nowadays less commonly—as Ca-chloride is the treatment of choice. Most cows with milk fever can be treated successfully with Ca salt solutions providing 8 to 10 g of Ca (Ca-borogluconate is 8.3% Ca). The dose rate of milk is frequently under discussion. A typical dose is 4 g Ca, additional Ca should be provided to overcome the ongoing losses in milk. Underdosing increases the chances of incomplete response, with inability of the cow to rise, or of relapse, whereas considerable overdosing may result in potentially fatal cardiac toxicity. Additional subcutaneous administration of Ca-borogluconate (500 mL of 23% Ca-borogluconate by slow IV injection with cardiac auscultation; this provides 10.7 g of Ca. Although the calculated Ca deficit in a recumbent periparturient dairy cow is 4 g Ca, additional Ca should be provided to overcome the ongoing losses in milk. Underdosing increases the chance of incomplete response, with inability of the cow to rise, or of relapse, whereas considerable overdosing may result in potentially fatal cardiac toxicity. Additional subcutaneous administration of Ca-borogluconate (500 mL) markedly decreased the relapse rate in cattle receiving 500 mL of Ca-borogluconate IV for the treatment of hypocalcemia.

The standard rate of administration is a rapid IV administration of the calculated dose of Ca-borogluconate over a period of 15 minutes. The maximum safe rate of Ca administration in cattle was determined to be 0.07 mEq of ionized Ca per kg body weight per minute, which is equivalent to 0.065 mL of a 23% Ca-borogluconate per kg body weight per minute. An average nonhypocalcemic 600-kg cow could therefore safely be treated with intravenous Ca-borogluconate (23%) at an infusion rate of 39 mL/min. Immediately following IV administration of Ca-borogluconate over a period of 12 to 15 minutes, treated animals are commonly markedly hypercalcemic (up to 6 mmol/L or 24 mg/dL). The plasma Ca concentration will then gradually decline over a period of several hours. Although the direct effect of intravenously administered Ca does not last for more than 6 to 8 hours, this transient correction of hypocalcemia in most cases is not only associated with clinical recovery of recumbent animals, but also with improved feed intake and enhanced gastrointestinal motility, which will result in improved intestinal Ca absorption. This latter effect, which relies on the availability of adequate amounts of Ca for absorption in the digestive tract, is responsible for the sustained correction of hypocalcemia observed in most cases. However, in some cows, mechanisms regulating the Ca homeostasis are less effective or the oral Ca supply is insufficient, and subclinical or clinical hypocalcemia may recur. For this reason, it is astute to follow up on intravenously treated animals with oral supplementation of Ca salts for 1 to 2 days.

Because of concerns with these rapid and short-lived peaks in plasma Ca after rapid infusion of Ca salt solutions, it has been suggested that slower IV infusion might be safer and more effective. The slow infusion of a Ca solution via an IV indwelling catheter over 6 hours was compared with the conventional single IV administration of 600 mL of a 40% Ca-borogluconate and 6% Mg-hypophosphite solution over 15 minutes in cows recumbent with milk fever. Cows receiving the rapid infusion responded more quickly, stood sooner, and returned to normal demeanor more quickly. The slow infusion consisted of 200 mL IV over a 10-minute period, with the remaining 400 mL added to 10 L of a solution of 90 g sodium chloride and 500 g glucose and given via IV drip over a 6-hour period at a rate of 1.7 L/h. In cows treated rapidly, the serum Ca and magnesium levels increased rapidly compared with the infused cows. In sheep and goats, the recommended amount is 15 to 20 g IV with an optional 5 to 10 g SC. Sows should receive 100 to 150 mL of a similar solution IV or SC.

**Routes of Administration**

**IV Route**

The IV route is preferred because the response is rapid and obvious. The heart should be auscultated throughout the IV administration for evidence of gross arrhythmia, bradycardia, and tachycardia. Although bradycardia is a normal response to Ca administration in hypocalcemic animals and is of no concern, the IV administration should be interrupted in case arrhythmia or pronounced tachycardia is noticed. If the cardiac irregularity continues, the remainder of the solution can be given subcutaneously. The best recommendation is to give as much of the solution as possible intravenously and the remainder subcutaneously. The common practice of giving half the dose intravenously and half subcutaneously is a reasonable compromise because with this method there are fewer relapses. If a cow has been previously treated subcutaneously by the farmer, additional Ca given intravenously may cause toxicity if the improved circulation enhances the absorption of the subcutaneous Ca.

Toxicosis occurs very susceptible to the IV administration of Ca-borogluconate, and death may occur. In such cases the heart rate increases markedly (up to 160 bpm); there is respiratory distress, trembling, and collapse; and the cow dies within a few minutes. SC or IV administration is preferred in cows with severe toxemia as a result of aspiration pneumonia, metritis, and mastitis.

**Typical Response to Intravenous Ca-Borogluconate**

Cows with milk fever exhibit a typical pattern of response to Ca-borogluconate IV if the response is favorable, including:

- Belching
- Muscle tremor, particularly of the flanks and often extending to the whole body
- Slowing and improvement in the amplitude and pressures of the pulse
- Decrease of the heart rate
- Increase in the intensity of the heart sounds
- Sweating of the muzzle
- Defecation

The feces are in the form of a firm fecal ball with a firm crust and covered with mucus. Urination usually does not follow until the cow stands. A slight transitory tetany of the limbs may also be observed. Many cows will eat and drink within minutes following successful treatment if offered feed and water.

In general, recovery can be expected in 75% of cases within 2 hours; in 10% recovery is complicated by one of the diseases discussed earlier, and 15% can be expected either to die or to require disposal. Of those that recover after one treatment, 25% to 30% can be expected to relapse and require further treatment.

**Unfavorable Response to Intravenous Ca-Borogluconate**

An unfavorable response is characterized by a marked increase in heart rate in cows affected with toxemia and bradyarrhythmia in animals developing an atrial block as a result of Ca overdosage. Overdosage may occur when a standard dose is administered to quickly, when an excessive dose is administered, when repeated doses are administered in excess of requirements, or when an individual with increased sensitivity to Ca is treated. Toxicity can, for instance, occur when farmers treat cases unsuccessfully by multiple SC injections and these are followed by an IV dose. When the peripheral circulation is poor, it is probable that the calcium administered subcutaneously is not absorbed until the circulation improves following the IV injection, and the large doses of Ca then absorbed cause acute toxicity.

Increased sensitivity to Ca has been reported in toxic animals with coliform mastitis or toxic metritis and in cows with severe ketosis or hepatic lipidosis. Hypokalemia that is common in anorectic animals may present a further factor predisposing to increased sensitivity of the heart muscle to excessive Ca doses. Sudden death may also occur after calcium injections if the cow is affected with toxemia and bradyarrhythmia or pronounced tachycardia is noticed. If the cardiac irregularity continues, the remainder of the solution can be given subcutaneously. The best recommendation is to give as much of the solution as possible intravenously and the remainder subcutaneously. The common practice of giving half the dose intravenously and half subcutaneously is a reasonable compromise because with this method there are fewer relapses. If a cow has been previously treated subcutaneously by the farmer, additional Ca given intravenously may cause toxicity if the improved circulation enhances the absorption of the subcutaneous Ca.

**Typical Response to Intravenous Ca-Borogluconate**

Cows with milk fever exhibit a typical pattern of response to Ca-borogluconate IV if the response is favorable, including:

- Belching
- Muscle tremor, particularly of the flanks and often extending to the whole body
- Slowing and improvement in the amplitude and pressures of the pulse
- Decrease of the heart rate
- Increase in the intensity of the heart sounds
- Sweating of the muzzle
- Defecation
The SC administration of Ca solutions also because these formulations are highly caustic. containing Ca-chloride should be avoided formulations containing Ca-gluconate or Ca-gluconate are suitable for SC administration solutions. 11 Although most dehydration because absorption in these inappropriate with severe hypocalcemia or Subcutaneous treatment with Ca solutions is low cost and a small volume required to ride formulations have the advantage of but they are highly caustic and may cause Subcutaneous treatment with Ca solutions is inappropriate with severe hypocalcemia or dehydration because absorption in these animals is impaired, which may result in a markedly delayed treatment effect. The amount of Ca administered per injection site should be limited to 1 to 1.5 g, which is equivalent to 50 to 75 mL of most commercial Ca infusion solutions. 11 As most solutions containing Ca-glucuronate or Ca-borogluconate are suitable for SC administration, the SC administration of salt solutions containing Ca-chloride should be avoided because these formulations are highly caustic. The SC administration of Ca solutions also containing glucose, particularly at higher concentrations, is discouraged because concentrated glucose can result in pronounced tissue irritation. 5 Administration of 500 mL of a 23% Ca-borogluconate solution over 10 injection sites was associated with an increase of the plasma Ca concentration of over 15% within 30 minutes; the plasma Ca concentration returned to baseline concentrations within 6 hours of treatment.8 Oral Route Or administration of different Ca salts has been practiced for decades. Oral formulations are commonly based on Ca-chloride (CaCl₂) and Ca-propionate. Calcium chloride formulations have the advantage of low cost and a small volume required to administer an appropriate dose of 50 g Ca, but they are highly caustic and may cause severe damage of the digestive tract mucosa exposed to the concentrated formulation. Repeated treatment with CaCl₂ may furthermore result in uncompensated metabolic acidosis in treated animals. 11 In contrast, Ca-propionate formulations require a higher volume to provide the same amount of Ca and are absorbed at a slower rate but are less injurious to tissue and do not alter the acid–base equilibrium. In these formulations, the availability of propionate, which is a glucose precursor, has been marketed as a further potential advantage, but studies investigating the effect of the gluconate contained in these products failed to identify any positive effects on plasma glucose, insulin, or NEFA concentration in cows treated with Ca-gluconate. 12 Oral CaCl₂ formulations typically contain 50 g of Ca and increase the plasma Ca concentration within 30 minutes and for at least 6 hours. 5, 8 Oral Ca formulations should only be administered to cattle with undisturbed swallowing ability, which precludes their use as first-line treatment in animals in an advanced stage of clinical hypocalcemia.

Failure to Respond to Treatment
A failure to respond favorably to treatment may be the result of an incorrect or incomplete diagnosis, or inadequate treatment. A poor response to treatment includes: (1) no observable changes in the clinical findings immediately following the calcium administration, or (2) the animal may respond to the calcium in all respects with the exception of being unable to stand for varying periods of time following treatment. An inadequate response also includes relapse after successful recovery, which usually occurs within 48 hours of the previous treatment. The needs of individual animals for Ca replacement vary widely depending on many factors, such as the body weight, milk yield, age, and degree of hypocalcemia. Incomplete responses may be more common in older cows and in cases of inability of the normal mechanisms to maintain serum Ca levels during the period of sudden changes in the equilibrium input and output of the extracellular Ca pool. The duration of the illness and the severity of clinical signs at the time of first treatment also affect the treatment response. In an extensive field study, there were no downer cows or deaths in cows still standing when first treated, 13% of downers and 2% of deaths occurred in cows in sternal recumbency when first treated, and 37% of downers and 12% of deaths occurred in cows in lateral recumbency when first treated. Therefore, in general, the longer the period from onset of milk fever to treatment, the longer the period of posttreatment recumbency and the higher the case-fatality rate. The best procedure to follow if response does not occur is to revisit the animal at 6- to 12-hour intervals and check the diagnosis. If no other cause of the recumbency can be determined, the initial treatment can be repeated on a maximum of three occasions. Beyond this point, further calcium therapy is seldom effective.

GENERAL MANAGEMENT AND CLINICAL CARE PROCEDURES
The care of the cow and the calf following milk fever is important. If the cow is recumbent for any length of time, she must be kept propped up in sternal recumbency and not left in lateral recumbency, which may result in tympany, regurgitation, and aspiration pneumonia. The cow should be rolled from side to side every few hours and provided with adequate bedding or moved to a suitable nonslip ground surface. In extreme climatic conditions, erection of a shelter over the cow is advisable if she cannot be moved to permanent shelter. If a cow is recumbent for more than 48 hours, occasional assisted lifting using appropriate cow lifters should be considered. However, heroic measures to get cows to stand should be avoided. Gentle nudging in the ribs or the use of an electric prod are the maximum stimulants advised. The best assistance that can be given to a cow attempting to stand is a good heave at the base of the tail when she is halfway up.

TREATMENT AND CONTROL
Treatment
Calcium gluconate (equivalent to 8 to 12 g Ca/Cow IV or SC as single dose) (R-1)
Calcium borogluconate (equivalent to 8 to 12 g Ca/Cow IV or SC as single dose) (R-1)
Calcium chloride (equivalent to 8 to 12 g Ca/Cow IV as single dose) (R-2)
Calcium chloride (equivalent to 50 g Ca/Cow) PO q12 for 48h (R-1)
Calcium propionate (equivalent to 50 g Ca/Cow) PO q12 for 48h (R-2)

Control
Reduce dietary calcium intake 2 to 3 weeks before calving to less than 20 g Ca/cow/day (R-1)
Reduce dietary potassium content as much as possible in late gestation (in any case, below 2% in feed dry matter) (R-1)
Provide adequate dietary magnesium in late gestation (>0.4% of feed dry matter) (R-1)
Anionic salts mixed into feed to obtain a dietary cation–anion difference of –100 to –150 mEq/kg of feed dry matter for at least 2 weeks before calving (R-1)
Zeolite A (250 to 500 g/cow/day) PO q24h for at least 2 weeks before calving (R-2)
Supplement diet in late gestation with vitamin D (R-1)
Vitamin D₂ (10 to 20 million IU/cow IM as single dose 3 to 7 days before expected calving) (R-2)
Vitamin D₂ (10 to 20 million IU/cow PO for at least 7 days before expected calving) (R-2)
Calcium chloride (equivalent to 50 g Ca/cow PO q12h for 48 hours from the time of parturition) (R-1)
Calcium propionate (equivalent to 50 g Ca/cow PO q12h for 48 hours from the time of parturition) (R-2)
Partial milking during the first days of lactation (R-3)
Udder insufflation in the first days of lactation (R-3)
When the incidence of milk fever increases to above 10% of high-risk cows (third or later lactations), a specific control program is necessary. When the incidence is low, a specific control program may not be economical, and the alternative is to monitor cows carefully at the time of parturition and for 48 hours after parturition and treat affected animals during the first stage of the disease if possible.

Strategies for prevention of periparturient hypocalcemia in general are based on one of following approaches:
- Reduction of dietary Ca available for intestinal absorption during the dry period
- Induction of mild to moderate acidosis during the last weeks of gestation
- Supplementation of vitamin D during the dry period
- Oral Ca supplementation around parturition
- Parenteral Ca administration around parturition
- Partial milking
- For purposes of optimal nutritional management of dairy cows that are fed prepared feeds (not pasture based), the dry period is frequently divided into two distinct portions: cows in the early and middle part of the dry period (far-off or regular dry-cow group) and cows in the final 2 to 3 weeks before their calving date (prefresh, transition, close-up, near, lead-feeding, or steam-up group). Large herds may have additional subgroups of dry cows depending on management circumstances and facilities available. Special attention must be given to the mineral nutrition of the close-up group. Minerals should be provided to close-up cows in known quantities, either as part of a dry-cow group or a total mixed ration (TMR).

**Reduction of Dietary Calcium Available for Intestinal Absorption**

**Dietary Calcium Concentration in Late Gestation**

Diet high in Ca during the prepartum period can result in a high incidence of milk fever, and diets low in Ca will reduce the incidence of milk fever in dairy cows. Feeding more than 100 g of Ca per cow per day during the dry period is associated with an increased incidence of milk fever. An adult cow requires only around 30 g/daily of Ca to meet maintenance and fetal demands in the last 2 months of late gestation. Low-Ca diets (<20 g [Ca/cow]/d) fed during the last 2 weeks before parturition are effective in reducing the occurrence of clinical milk fever. The low levels of dietary Ca push the organism into a negative Ca balance before calving, which activates the homeostatic mechanisms before the Ca losses through the mammary gland begin. These mechanisms include the secretion of PTH, which increases renal reabsorption of Ca within minutes, stimulates Ca resorption from bone within hours to days, and stimulates renal vitamin D metabolism to toward production of 1,25-(OH)2D within hours or days. The 1,25-(OH)2D stimulates the active transport of Ca across the intestinal epithelial cells. At the time of calving, the cow is more efficient in absorbing Ca from the digestive tract and mobilizing Ca from bone reserves. At least 14 days of a low-Ca diet are required to be effective in minimizing the incidence of milk fever.

**Practicality of Feeding Diets Low in Calcium**

There are practical problems with the implementation of the recommendation to feed diets low in Ca. Most farms utilizing home-grown forages, especially alfalfa, find it difficult to obtain forages that are low in Ca. A low-Ca diet can be achieved by replacing some or all alfalfa hay in the dry-cow diet with grass hay and using additional corn silage and concentrates. When feeding grass hay to dry cows, attention must be paid to the dietary potassium content of the dry-cow ration because high potassium intake tends to alkalize the organism and thereby impair the efficacy of bone mobilization.

**Binding Dietary Calcium**

If formulating a diet low enough in Ca to induce a negative Ca balance is a problem, it is possible to reduce the digestibility of dietary Ca by adding a substance to the feed capable of binding dietary Ca and making it less available for intestinal absorption. The oral administration of sodium aluminum silicate or zinc oxide to cows in late lactation binds dietary Ca, thereby inducing a negative Ca balance. Supplementing the dry-cow ration with sodium aluminum silicate (zeolite A) at the rate of 1.4 kg of zeolite pellets per day (700 g of pure zeolite A) for the last 2 weeks of pregnancy results in a significant increase in plasma Ca and 1,25-(OH)2D around calving. It should, however, be noted that this amount of pellets is equivalent to over 10% of the dry matter feed intake of a dairy cow in the last days before calving. Plasma magnesium and inorganic phosphate levels also decrease, which has raised concerns with the use of these salts. Feed intake was decreased by over 20% in zeolite-treated cows compared with control cows, which was associated with significantly increased betahydroxybutyrate concentrations after calving. Lower doses of zeolite A in the range of 250 g of pure zeolite A resulted in a less pronounced feed intake depression while significantly increasing the plasma Ca concentration around calving in cattle in third or higher lactation. This lower dose of zeolite A still was associated with decreased plasma inorganic phosphate concentrations, whereas plasma magnesium was unaffected.

Feeding a vegetable oil supplement (soya bean oil) to pregnant pastured dairy cattle during the last 2 to 3 weeks of pregnancy is effective in preventing milk fever and increases milk solids production in early lactation. The same supplement has been used to stimulate Ca absorption and reduction in susceptibility to fasting-induced hypocalcemia in pregnant ewes. Following supplementation, the ewes are fasted overnight to challenge calcium homeostasis. Following fasting, there is a greatly increased capacity to absorb calcium.

**Level of Phosphorus in Diet**

Increased levels of dietary phosphorus, greater than 0.5% kg dry matter, can increase the incidence of milk fever. The increased intake increases the serum level of phosphorus, which has an inhibitory effect on renal enzymes catalyzing the activation of vitamin D3. Decreased availability of bioactive vitamin D3 results not only in reduced intestinal phosphate, but also reduced Ca absorption.

**Calcium-to-Phosphorus Ratio in Diet**

Although the ratio of Ca to phosphorus in the diet is of relevance in monogastric species, it is now recognized that this ratio is of little importance in ruminants, provided that the minimum requirements for both minerals are met. The presumable explanation for this difference from monogastric species is the high concentration of phosphorus in saliva in combination with the large volumes of saliva produced per day that are entering the rumen. The salivary P content will thus greatly distort the ratio of calcium to phosphate of the ingested diet.

**Induction of Mild to Moderate Acidosis During Late Gestation: Cation–Anion Difference**

A more reliable method of controlling milk fever in dairy cows is to manipulate the dietary cation–anion difference (DCAD) during the prepartum period. Diets high in cations, especially potassium and sodium, tend to induce milk fever compared with those high in anions, primarily chloride and sulfur, which can reduce the milk-fever incidence. When the dietary cation concentration is increased and these cations are absorbed from the digestive tract, they tend to increase the plasma strong ion difference (SID), thereby creating a metabolic (or strong ion) alkalosis. Conversely, dietary anions absorbed from the gut decrease the SID, which causes metabolic acidosis. The feeding of diets containing an excess of anions relative to cations, thus with a low DCAD, will result in metabolic acidosis. Two PTH-dependent functions, bone resorption and renal production of 1,25-(OH)2D, are enhanced in cows fed diets with added anions, and thus a low DCAD, which increases their resistance to milk fever and hypocalcemia.
The DCAD is expressed in milliequivalents per kilogram of dry matter (mEq/kg DM) or in some instances in mEq/100 g DM. Several different equations have been proposed for the calculation of the DCAD; for convenience, the most commonly used is DCAD\(_4\) = (Na\(^+\) + K\(^+\)) − (Cl\(^−\) + S\(^−\)), which only considers the four (thus DCAD\(_4\)) quantitatively most important dietary ions. Other electrolytes, such as calcium, magnesium, and phosphorus, also affect the acid–base status and are included in some of the DCAD equations proposed in the literature. The impact of these minerals on the actual DCAD value is, however, considered to be minor because of the relatively low content of these elements in the ruminant diet.

The equation assigns the same acidification potency to each milliequivalent of Cl and S, although Cl is absorbed to a greater extent than S and thus has a higher potential of acidification. Such effects are considered in more developed DCAD equations that include a corrective factor for each element accounting for these differences in digestibility.

Calculation of the DCAD requires converting the dietary content of each mineral from g/kg or mg/kg to into charges per kg (equivalents/kg). The mass expressed in mmol/kg DM is equal to mEq/kg for all monovalent elements, with only one charge per molecule, such as Na\(^+\), K\(^+\), and Cl\(^−\). Divalent elements, such as Mg\(^2+\), Ca\(^2+\), and S\(^2−\), have two valences per molecule; thus 1 mmol is equivalent to 2 mEq. Table 17-6 provides reference values for determining the mEq of important electrolytes and converting from g/kg or percent diet dry matter (DM) to mEq/kg. Once milliequivalents are calculated, the DCAD can then be determined by subtracting the anions from the cations. The following equation can be used to calculate the DCAD from the percent element in the diet dry matter: mEq/100 g DM = [(%Na + 0.023) + (%K + 0.039)] − [(%Cl + 0.0355) + (%S + 0.016)].

Based on current evidence, the range that achieves the lowest incidence of milk fever is a DCAD of −10 to −15 mEq/100 g DM (−100 to 150 mEq/kg DM). Such a diet should be fed for 2 to 3 weeks before calving. This rate of supplementation is reported not to affect DM intake or energy balance before or after calving. A more moderate rate of supplementation to reduce the DCAD to 0 mEq/100 g dietary DM also did not decrease feed intake or energy status, but was less effective in preventing parturient hypocalcemia.

Most typical diets fed to dry cows have a DCAD of about +100 to +250 mEq/kg DM. Addition of a cationic salt such as sodium bicarbonate to the dry-cow diets increases the DCAD and thereby increases the incidence rate of milk fever. Decreasing the dietary potassium content, by choosing ration ingredients low in potassium or adding an anion source or a mixture of anionic salts containing Cl and S to the diet, lowers the DCAD and reduces the incidence of milk fever. Commonly used sources of anion salts include the Cl and S\(_4\) salts of calcium, ammonium, and magnesium. The phosphate salts have not been used because they are only weakly acidifying.

The addition of anions to the diet to reduce dietary DCAD is limited in quantity because of problems with the palatability of the anionic salt sources commonly used. If the DCAD is greater than 250 mEq/kg, for instance, because of excessive amounts of dietary potassium, it is difficult to add enough anionic salts to lower the DCAD to the recommended −100 mEq/kg of the diet without affecting palatability. In these cases the first objective should be to reduce the dietary cation content as much as possible and only then determine the amount of anions required to achieve the proposed DCAD.

In one study, the incidence of milk fever was 47% when prepartum cows were fed a ration with a DCAD of +330.5 mEq/kg dietary DM and 0% when the prepartum ration had a balance of −128.5 mEq/kg dietary DM. The incidence of milk fever was reduced by the addition of chloride and sulfur in excess relative to sodium and potassium in the diet.

Although it has been proposed that dry cows on low-DCAD diets to control milk fever need to be supplemented with dietary Ca to compensate for increased renal Ca losses resulting from acidification, this recommendation is not undisputed. Several studies showed that the dietary Ca content of dry cows on a high-chloride diet had no effect on the occurrence rate of clinical hypocalcemia. Feeding rations with a dietary Ca between 0.5% and 1.5% did not alter the efficacy of low-DCAD diets, but high-Ca diets fed to dry cows were associated with slightly decreased feed intakes compared with control cows. In any case, DCAD diets should not be combined with low-Ca diets or the use of Ca binding compounds in the feed before calving.

Monitoring the urine pH can be a useful aid to find the effective dose of anionic salts in the close-up ration. Adequate activation of mechanisms increasing Ca absorption from the gut and release from bone through mild to moderate acidification of the organism is associated with a decline of the urine pH below 7.0. Urine pH values of dry cows on a low-DCAD diet above 7.0 suggest that the degree of acidification may not be sufficient to effectively mobilize Ca through the mechanisms previously described. It is suggested that a urine pH between 6.0 and 7.0 is ideal.3

Anionic Salts for Acidification of Prepartum Diets for Dairy Cows

Several anionic salts are available for addition to the ration of prepartum dairy cows to prevent milk fever. Generally, acidification of the cows occurs within approximately 36 hours following addition of the anionic salts to the ration; it also takes less than 36 hours for the cow to return to an alkaline state following removal of the salts from the diet. The relative acidifying activity of anionic salts commonly used to prevent milk fever has been evaluated. Salts of chloride have about 1.6 times the acidifying activity of sulfate. Calcium and magnesium, which are usually not included in the DCAD equation, have a small but significant alkalining effect when accompanied by chloride or sulfate. The ranking of the anion sources tested at a dose of 2 Eq/day, from most to least potent urine acidifier, was hydrochloric acid, ammonium chloride, calcium chloride, calcium sulfate, magnesium sulfate, and sulfur. Magnesium sulfate is the most palatable of the anionic salts commonly supplemented, and calcium chloride is the least palatable. It is best to add the anionic salts to a total mixed ration. Because of the low incidence of milk fever in heifers, there is no need to feed anionic salts to heifers.

Anionic salts can reduce dry matter intake when more than 300 mEq of anions/kg diet DM are supplemented in the diet. The reductions in dry matter intake are commonly ascribed to decreased palatability, but they may represent a response to the metabolic acidosis induced by the salts. The duration of feeding anion salts ranges from 21 to 45 days before expected parturition. At least...
5 days of consumption are necessary for maximal benefit.

**Ammonium Chloride.** Ammonium chloride is more effective than most other salts as an acidifier. The addition of ammonium chloride salts to prepartum diets offers considerable promise as a practical and reliable method of control of milk fever. Within the European Union, ammonium chloride is currently permitted as a pharmacologically active substance in veterinary medicinal products, but not as a zootechnical or feed additive in cattle. Experimentally, the addition of ammonium chloride and ammonium sulfate, each at 100 g/head per day, to the prepartum diets 21 days before parturition decreased the incidence of milk fever from 17% in the unsupplemented group to 4% in the supplemented group.

**Strategies for Supplementing Anion Sources**

A systematic protocol for the addition of anions to a prepartum diet and monitoring of its effects is as follows:

1. Perform macromineral analysis of all available forages for prepartum cows.
2. Select feed ingredients with a low DCAD, especially those low in potassium.
3. Calculate the DCAD of the diet without any supplemental anion sources. If the DCAD is more than +250 mEq/kg, then priority must be given to reduce this value by replacing some of the forage with a lower-DCAD forage.
4. Balance dietary magnesium at 0.40% DM by adding additional magnesium chloride or magnesium sulfate. Magnesium chloride is preferred.
5. Evaluate the feeding management of the prepartum cows. Ensure adequate feeding space and quality of feed.
6. Add supplemental chloride and/or sulfur to the prepartum cow diet to lower DCAD to about –150 mEq/kg DM.
7. Evaluate the dietary nonprotein nitrogen (NPN) and degradable intake protein (DIP) of the diet. If NPN is more than 0.50% of the diet DM or DIP is more than 70% of crude protein, then reduce the amount of ammonium salts or other NPN or DIP sources in the diet.
8. Monitor dry matter intake of the prepartum-cow group.
9. Consider more palatable anion sources or a reduced dose of anion sources if dry matter intake is depressed.
10. After 1 week of feeding anionic salts, monitor the pH of close-up dry cows. Urinary pH is an accurate indication of optimal dietary acidification. Collect urine from at least six cows at one time and average the urinary results. Adjust the dose of supplemental anions to achieve an average urinary pH of between 6.0 and 7.0.

**DCAD and Acid–Base Balance of Dairy Cows on Pasture-Based Diets**

The dairy industries of southern Australia and New Zealand are based largely on fresh pasture and pasture silage, and grazed pasture is the key determinant of the DCAD. The concentration of potassium is often in excess of 4%, and the DCAD greater than 500 mEq/kg DM, in pasture-based diets, yet the incidence risk of milk fever is not higher than those in other countries where dietary potassium is much lower. For a considerable part of spring and early summer, the DCAD of pasture in those countries may be in excess of +500 to +700 mEq/kg DM. The variation in the DCAD of pasture and the difficulty in accurately assessing dry matter intake make an accurate reduction in DCAD difficult to achieve practically. Pasture cation–anion difference in those conditions is not greatly influenced by stocking rate or associated management practices. The urine pH of grazing dairy cows in south eastern Australia remains relatively constant throughout the year despite changes in stage of lactation, management practices, season, weather, and large changes in DCAD. The DCAD of pasture throughout the year in south eastern Australia ranges from 0 to 800 mEq/kg DM and is often outside the levels previously recommended for optimal performance of lactating cows. For spring-calving herds on pasture, a high DCAD at the time of parturition presents practical problems in administering the large amounts of anionic salts required to lower urine pH and to decrease the incidence of hypocalcemia.

In these pasture-based systems, sulfur (S) is considered a more important dietary constituent in determining the risk of hypocalcemia than either chloride or potassium. The absorption efficiency of S is less than either Cl or K and would not be expected to incur the same change in systemic pH. Thus its importance in hypocalcemia prevention does not fit with the current understanding of how manipulation of DCAD influences calcium homeostasis. Studies indicate that precalving dietary S is more important in the control of hypocalcemia than either K or Cl concentration. Although the effects of a systemic acidosis on Ca absorption is accepted, the effect of S on periparturient Ca homeostasis when absorption of S is low in comparison to Cl, Na, or K suggest that there are mechanisms involved that are not related to acid–base balance. An increased incidence of milk fever may occur in pastured-based dairy when the diet is supplemented with Cl and S, even though calcium absorption, as indicated by urine calcium concentration, increases. The increased incidence may be a result of a greater demand for dietary calcium after calving following a reduction in the pH of body fluids precalving and the fact that pasture-based diets, as opposed to total mixed rations, are generally low in calcium. Supplementation of cows with calcium after calving increased plasma calcium concentration on the day of calving and during the subsequent 14 days. Milk production was not affected by pre- or postcalving treatments.

Experimentally, the application of potassium fertilizer on pasture resulted in a DCAD ranging from 350 to 535 mEq/kg DM, but calcium homeostasis in pasture-based dairy cows was not changed. Plasma concentrations were increased, and the risk of clinical periparturient hypocalcemia was reduced, by MgCl₂ and MgSO₄ delivered by 150 g MgCl₂, 200 g MgSO₄, and 35 g MgO/head daily for 21 days prepartum. After calving, cows were supplemented with 150 g CaCO₃/head per day for 4 days. Improvements in calcium homeostasis were not the result of an altered systemic pH.

The optimum DCAD for lactating cows grazing fresh pasture and the effect of deviating from the optimum on milk production have been examined under experimental manipulation of the dietary DCAD using a drench in early-lactation dairy cows in New Zealand. Dietary cation–anion differences ranged from +23 to +88 mEq/100 g of DM. As DCAD increased, there was a linear increase in blood pH and HCO₃⁻ concentration and blood base excess. Plasma concentrations of Mg, K, and Cl declined as DCAD increased and Na increased. Urinary excretion of Ca decreased as DCAD increased. Increasing DCAD did not significantly affect milk yield or milk protein, but the concentration and yield of milk fat increased linearly. Milk production results suggest that DCAD for optimal production on pasture diets may be higher than the +20 mEq/100 g DM previously identified for total mixed rations.

**Summary of Macromineral Nutritional Strategies for the Prevention of Hypocalcemia in the Soon-to-Calve or Transition Dairy Cow in Pasture-Based Systems**

Circumstances and principles can be summarized as follows:

- **When dairy cows are dried off, they are commonly moved onto nonirrigated pastures until calving. In the summer, dry cows would be put onto actively growing tropical pasture, whereas in autumn, winter, and spring, the pasture is most likely to be tropical pasture carried over from the previous summer. This carryover pasture is likely to be supplemented with medium-quality hay, silage, and grain or molasses 2 to 3 weeks before calving. Anionic salts have been added to these diets.**
  - The DCAD on a yearly basis ranges from 0 to 80 mEq/100 g DM.
  - The incidence of milk fever in Australia ranges from 1.6% to 5.4%, but in some
years the incidence in individual herds may reach 20%. The incidence of subclinical hypocalcemia can range widely: up to 40% of apparently normal cows had subclinical hypocalcemia (total plasma calcium < 1.9 mmol/L during the first 12 days of lactation).

- In temperate climates, reducing dietary calcium to recommended low levels can be difficult to achieve, but in tropical pastures the levels are already low.
- Excessive levels of potassium may be the most important dietary risk factor for milk fever in Australian feeding systems. Potassium contents of pastures may be as high as 4% to 5% of DM. The use of potassium fertilizers exacerbates the problem. Potassium and consequently dietary DCAD peak in winter and are lowest in autumn. The majority of cows in Victoria, Australia, calve in winter to early spring when the potassium levels are high.
- Hypomagnesemia influences calcium homeostasis, and diets high in potassium reduce the concentration of plasma magnesium. Magnesium supplementation of the transition diet should be done to ensure that magnesium requirements are met (0.4% of DM).
- Excessive dietary phosphorus increases the concentration of phosphorus in plasma, which can induce hypocalcemia and increase the incidence of milk fever at calving. Supplements likely to increase the dietary intake of phosphorus above 40 g/day should not be fed to cows in the weeks before calving.

Supplementation of Vitamin D During the Dry Period

Parenteral Vitamin D₃ Application
In an attempt to reverse the negative Ca balance of susceptible cows at the onset of lactation, the administration of vitamin D₃ and its analogs has been used to increase intestinal Ca absorption. Vitamin D₃ is hydroxylated in the liver, and the resulting metabolite is 25-hydroxycholecalciferol. This is metabolized in the kidney to 1,25-dihydroxycholecalciferol, which has an active hypercalcemic effect but is difficult to synthesize. One of its analogs, 1-α-hydroxycholecalciferol, is as active, is easy to prepare, and is used pharmacologically. A single parenteral dose of 10 million IU per cow of intramuscular (IM) vitamin D₃, given 2 to 8 days before parturition is often recommended, although the dose recommendation based on body weight (1 million units per 45 kg BW) has given consistently better results. Two important inconveniences of the parenteral treatment with vitamin D₃ are the narrow time frame before calving during which vitamin D₃ must be administered to be effective and the narrow therapeutic range of the drug. If the cow fails to calve within 10 days of treatment, another 10 million units may need to be administered because cows treated more than 10 days before calving are at increased risk of developing clinical milk fever. Repeated treatment is associated with soft tissue calcification, particularly after repeated injections. Pregnant cows are more susceptible to calcification than nonpregnant animals. Whereas single doses below 10 million units to an adult cow were found to be considerably less effective in preventing clinical milk fever, a dose of 17 million units was lethal for 75% of treated animals.

Another disadvantage of using injectable vitamin D₃ is that although it is effective in preventing clinical milk fever, it tends to result in significantly lower plasma Ca concentrations between 3 and 14 days postpartum compared with untreated control cows. Cows treated with injectable vitamin D₃ therefore are at decreased risk of developing clinical milk fever around parturition but may be at increased risk of subclinical hypocalcemia during the first weeks of lactation. The problem appears to be that the effect of the exogenous metabolite on intestinal Ca absorption declines, whereas its inhibiting effect on the renal enzymes activating endogenous vitamin D₃ is more sustained. Treated cows therefore appear to be impaired in their ability to produce sufficient 1,25-(OH)₂D₃ to maintain enhanced intestinal absorption of calcium in the first weeks of lactation.

Oral Vitamin D₃ Administration
Oral dosing with 20 million IU of vitamin D₃/d for 5 days to cows immediately before calving can markedly reduce the expected incidence of milk fever. Because the onset of action after oral treatment is more delayed than after injection, a cow must be treated for at least 5 days before calving for the treatment to be effective. The exact date of calving is often difficult to determine, and if the administration is discontinued for up to 4 days before calving, an unusually high incidence of the disease may follow, probably because of the depression of parathyroid activity that follows the administration. Toxicity of the oral treatment is considerably lower compared with injection. A dose of 30 million IU of vitamin D administered over 7 days was without obvious signs of toxicity. The danger of causing metastatic calcification, however, also exists; this has been produced with smaller doses (20 million IU daily for 10 days).

Oral Calcium Supplementation Around Parturition
The oral administration of easily absorbed Ca salts such as calcium chloride or calcium propionate providing the equivalent of 40 to 50 g calcium per dose as a bolus, gel, paste, or liquid, given in a single dose or repeated doses beginning 12 to 24 hours before calving and continuing to 24 hours after calving, is a common practice that will effectively increase the plasma Ca concentrations for at least 6 hours. Based on clinical studies, a treatment interval of 6 to 12 hours for the period around calving has been suggested. Depending on the type of formulation, its palatability, and the required treatment frequency, oral treatment can be more or less labor intensive, demanding, and invasive. Calcium chloride is highly soluble, resulting in a rapid increase of the plasma Ca concentration within 30 minutes, but it is also caustic and may result in epithelial lesions of the mucosa of the oropharyngeal region, esophagus, forestomachs, or abomasum. In contrast, Ca-propionate requires a larger volume to provide a similar amount of Ca and has a more delayed effect on the plasma Ca concentration, but it is less injurious and thus safer to administer. The combined administration of Ca together with propionate, which is a glucose precursor in the form of calcium propionate, has been used as a further supporting argument for the use of this compound around calving. However, studies investigating the effect of Ca-propionate on feed consumption, milk yield, plasma glucose, insulin, and NEFA concentration in periparturient cows failed to identify a beneficial effect.

- Prophylactic treatment with oral Ca formulations in contrast to parenteral Ca administration bears the advantage that it does not disturb mechanisms regulating the Ca homeostasis, but rather supports them by providing oral Ca while intestinal Ca absorption has been upregulated.

Parenteral Calcium Supplementation Around Parturition
Intravenous or subcutaneous administration of Ca-gluconate or Ca-borogluconate solutions to cattle around parturition is sometimes practiced because this approach may be perceived as a convenient and inexpensive method to control milk fever. However, increasing the plasma Ca concentration to supraphysiological levels, as often occurs after parenteral administration of therapeutically effective doses of Ca solutions, disturbs the endocrine circuits regulating calcium homeostasis by abruptly interrupting the PTH secretion that is essential to prevent excessive declines of the plasma Ca concentration around parturition. This disruption will result in a delay of the correction of the periparturient disequilibrium of the Ca balance, which has been documented in several studies. Cows treated prophylactically with Ca solutions parenterally have pronounced but transient hypercalcemia that is followed by decline of the plasma Ca concentration below pretreatment Ca concentrations within 12 hours. A recent study comparing IV Ca administration with oral Ca administration and no treatment in periparturient cows not showing clinical signs of milk fever revealed that plasma Ca concentrations were significantly
higher than those in orally treated and control cows only for the first 4 hours post-treatment, but they were below the Ca concentrations of orally treated cows from 24 hours until at least 48 hours posttreatment and below the values of untreated cows from 36 hours until at least 48 hours post-treatment. Parenteral administration of Ca solutions should therefore be(150,817),(959,825)

**Partial Milking**

Partial milking after calving has been proposed for decades as a strategy to decrease Ca losses through the mammary gland in early lactation. Although this practice evidently reduces the amount of Ca excreted through the mammary gland, studies investigating the effect of partial milk-out on the plasma Ca concentration in the first days of lactation failed to identify a beneficial effect.

**ACUTE HYPOKALEMIA IN CATTLE**

**SYNOPSIS**

Hypokalemia is most common in lactating dairy cattle and is secondary to the following:

- Anorexia resulting from clinical mastitis and retained placenta
- Upper gastrointestinal obstruction, particularly left-displaced abomasum, right-displaced abomasum, abomasal volvulus, and abomasal impaction
- Obligatory loss of potassium in milk (1.4 g potassium/L of milk)
- Hyperinsulinemia secondary to hyperglycemia and transcellular shift of extracellular potassium
- Sympathetic nervous system activation
- Aldosterone release in response to hypovolemia and the need for sodium retention
- Decreased whole-body potassium stores as a result of the relatively low muscle mass in dairy cows

In most cases, the hypokalemia is not severe enough to cause weakness and recumbency.

**ETIOLOGY**

Hypokalemia occurs commonly in lactating dairy cattle with prolonged inappetence (>2 days), but it is rare in adult ruminants with adequate dry matter intake and neonatal calves, lambs, and kids. Hypokalemia occurs more commonly in lactating dairy cows than beef cows or feedlot animals because of the additional loss of potassium in the milk, the lower muscle mass in dairy cows that results in decreased whole-body potassium stores, and the use of glycerogen and skeletal muscle protein for energy in early lactation.

Milk typically has a potassium concentration of 36 mmol/L. Hypokalemia occurs at increased risk for hypokalemia, and the incidence of hypokalemia in the postparturient period increases as milk production increases. Early-lactation dairy cows are in a marked state of negative energy balance; catabolism of intracellular glycerogen and protein leads to increased potassium excretion in urine and therefore whole-body potassium depletion because potassium is bound to glycogen.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine. Hypokalemia and whole-body potassium depletion is common in lactating dairy cattle receiving one or more injections of corticosteroids for ketosis that have mineralocorticoid activity, particularly isoflupredone acetate. The hypokalemic effect occurs because the mineralocorticoid activity of isoflupredone enhances renal and gastrointestinal (saliva and colon) losses of potassium. Hypokalemia reaches its nadir of approximately 60% to 70% of the normal value by 72 hours after the first of two 10-mg injections. Exogenous or endogenous insulin release secondary to hyperglycemia following IV dextrose administration or corticosteroid administration can lead to hypokalemia associated with the intracellular movement of potassium accompanying glucose; this is a shift in potassium and not whole-body depletion.

In general, alkalemia decreases serum potassium concentration, and acidemia increases serum potassium concentration. Hypokalemia therefore occurs commonly in ruminants with metabolic alkalosis. Experimental induction of metabolic alkalosis by oral administration of sodium bicarbonate in three Jersey cows caused marked metabolic (strong ion) alkalosis (base excess, 14 to 19 mEq/L), hypokalemia (2.6 to 3.1 mEq/L), and an increase in muscle potassium concentration of 6% to 10%, indicating an intracellular shift of potassium from the extracellular space to the intracellular space.

Whole-body depletion of potassium may be present in healthy dairy cattle immediately after calving, based on the results of potassium balance studies and studies documenting decreased skeletal muscle potassium content at calving and decreased
urinary potassium concentrations immediately after calving.25

**PATHOGENESIS**

Potassium homeostasis in adult cattle is determined by the balance between absorption of potassium from the gastrointestinal (GI) tract and subsequent excretion by the kidneys and salivary glands. Transport of potassium is passive in the small intestine and active in the colon under the influence of aldosterone. The most important hormone affecting renal and salivary potassium excretion is aldosterone, which is released from the zona glomerulosa of the adrenal gland in response to hyperkalemia and other factors. At least 95% of whole-body potassium is intracellular, with skeletal muscle containing 60% to 75% of the total intracellular potassium. Total potassium losses in lactating cattle are 75% in urine, 13% in feces (mainly endogenous loss), and 12% milk, with urine, fecal, and milk losses being obligatory. Marked changes in serum or plasma potassium concentrations alter the resting membrane potential of cells because the potassium gradient generated by Na-K ATPase is the main cause for the negative electric potential across cell membranes. Hypokalemia therefore alters the resting membrane potential and leads to clinically significant changes in cellular and organ function. Hypokalemia indicates whole-body depletion of potassium unless induced by hyperglycemia and hyperinsulinemia. 6,25

The potassium content of cattle has been estimated at approximately 2.2 g/kg BW. Lactating dairy cattle should be fed a diet containing at least 0.7% potassium on a dry-weight basis, although high-producing dairy cattle need a higher dietary potassium concentration, and potassium is frequently fed at 1.3% to 1.4% on a dry-weight basis. The absorption efficiency of potassium on a typical lactating dairy cow diet ranges from 74% to 88%, with potassium being absorbed in the small intestine and forestomach, with the former predominating. Rumen fluid in cattle usually has a potassium concentration of 24 to 85 mEq/L, and rumen fluid potassium concentration and potassium absorption are strongly dependent on intake. This indicates that increasing potassium intake (specifically, increasing rumen potassium concentration) will directly lead to increased potassium absorption. Studies in fed sheep have indicated a strong linear relationship between potassium absorbed from the rumen and rumen potassium concentration; however, it should be noted that the rate of potassium absorption depends also on whether the animal is fed or fasted. Fasting in sheep for 26 hours decreased rumen potassium concentration from 50 mmol/L to 24 mmol/L and decreased plasma potassium concentration from 4.2 to 3.7 mmol/L.

Potassium homeostasis is not considered to be under direct hormonal control in sodium-replete healthy lactating cattle because there is no association between plasma aldosterone concentrations and whole-blood or urine potassium concentrations.3 Anorexia is thought to play an important role in the development of hypokalemia in cattle because 24 to 48 hours are needed for the mammalian kidney to adjust to a reduction in dietary potassium intake.3 Dehydration also plays an important role in hypokalemia via aldosterone activation. There appears to be a gut or hepatoportal sensor that detects potassium intake and sends a signal to the kidney to increase potassium excretion in response to increased potassium ingestion, but the anatomic location of the sensor and the molecular pathway for signal transduction remain unknown. Nevertheless, activation of the gut/hepatoportal sensor means that there is increased potassium excretion by the kidney. The reason before there is a detectable increase in serum potassium concentration following increased potassium intake.

Relative to an in vitro potassium concentration of 5 mmol/L, decreases in tissue bath potassium concentration decrease the amplitude of contraction of the circular muscle of the cow abomasal corpus; this smooth muscle is responsible for the propulsion of abomasal chyme.4 Small, but nonsignificant, decreases in the force developed by abomasal smooth muscle from bulls is observed when in vitro potassium concentration is decreased from 5.4 to 2.0 to 3.0 mmol/L.2 Hypokalemia may therefore result in decreased abomasal emptying rate and consequently an increased risk of developing left-displaced abomasum, abomasal volvulus, and potentially retained placenta and metritis in dairy cattle. The relationship between potassium concentration and skeletal muscle tone has not been determined for cattle, but studies in humans suggest hypokalemia must be marked (<2.0 to 2.5 mEq/L) to decrease skeletal muscle tone.

**CLINICAL FINDINGS**

Affected animals have generalized muscle weakness, decreased gastrointestinal motility, and depression. Severely affected animals are unable to stand or lift their heads from the ground. Cows with severe hypokalemia (<2.0 mEq/L) are usually recumbent and profoundly weak, appear flaccid, and lie in sternal or lateral recumbency. They are unable to support the weight of their heads off the ground and commonly hold their heads in their flanks. Profound weakness of the lateral cervical muscles may occur. Anorexia is common. Cardiac arrhythmias are often detectable on auscultation, and atrial fibrillation may be present on electrocardiography.

Cardiac arrhythmias are associated with abnormal serum potassium concentrations, both hypokalemia and hyperkalemia. In an unpublished study of 110 adult cattle with atrial fibrillation, hypokalemia was commonly present before the induction of atrial fibrillation. Although there do not appear to be any large-scale studies examining the association between hypokalemia and cardiac arrhythmias in adult cattle, hypokalemia, hyperkalemia, and alkalosis are commonly present in lactating dairy cattle with left-displaced abomasum and atrial fibrillation. In a recent study, 2/15 lactating dairy cows with experimentally induced hypokalemia and alkalosis developed atrial fibrillation that resolved within 24 hours of administration of KCl, accompanied by an increase in plasma potassium concentration and a decrease in blood pH.7 Atrial fibrillation in other studies was diagnosed in 4/10, 2/14, and 5/17 cows with naturally acquired hypokalemia, and in 1/7 lactating dairy cows with experimentally induced hypokalemia following IM administration of two 20-mg doses of isoflupredone acetate at a 48-hour interval. Taken together, these findings suggest that hypokalemia plays an important role in the development of atrial fibrillation in adult cattle.

Signs of chronic potassium depletion in cattle include anorexia; pica characterized by hair licking, floor licking, and chewing of wooden partitions; rough hair coat; muscular weakness; irritability; paralysis; and tetany.

**CLINICAL PATHOLOGY**

The order of sensitivity/specificity in determining whole-body potassium depletion is as follows: skeletal muscle > serum/plasma > milk > erythrocyte/whole blood > urine > saliva.

**Skeletal Muscle Potassium Content**

Skeletal muscle potassium concentration is considered the most sensitive and specific method for assessing whole-body potassium status and therefore provides the gold-standard test. Skeletal muscle is considered the best tissue to sample because it contains approximately 75% of the whole-body stores of potassium. A standardized muscle should be evaluated in cattle because differences in potassium content of greater than 15% are present in individual animals, and this muscle-to-muscle variation is greater than that produced by breed.

**Plasma Potassium Concentration**

Determination of serum/plasma potassium concentration is required to confirm a suspected diagnosis of hypokalemia. A serum potassium concentration less than 2.5 mEq/L reflects severe hypokalemia, and most animals will be weak or recumbent. A serum potassium concentration of 2.5 to 3.5 mEq/L reflects moderate hypokalemia, and some cattle will be recumbent or appear weak, with depressed gastrointestinal motility. In addition to measurement of serum potassium concentration, determination of the serum concentrations of sodium, chloride,
calcium, and phosphorus and the serum activities of creatine kinase and aspartate aminotransferase can be very helpful in guiding treatment of cattle with hypokalemia. Serum potassium concentration is usually a little higher than plasma potassium concentration because platelet activation releases potassium. In summary, a serum/plasma potassium concentration below the normal range provides unequivocal evidence of hypokalemia unless there is concurrent hyperinsulinemia or alkalolemia. However, because more than 95% to 98% of whole-body potassium stores are intracellular, it is likely that serum/plasma potassium concentration is not as sensitive as skeletal muscle potassium content in indicating whole-body potassium depletion.

Milk Potassium Concentration
Milk potassium concentration is theoretically more sensitive than serum/plasma potassium concentration in detecting whole-body potassium depletion in individual cows because the milk concentration of potassium is constant for an individual cow. Potassium depletion in lactating dairy cows caused milk potassium concentration to decrease from 1.45 g/L to 1.28 g/L; this was a greater percentage decrease than that in the plasma or whole blood of cattle with whole-body potassium depletion. However, there is marked individual variation in the milk concentration of potassium in healthy cattle, with variations of up to 50% occurring between cows. This variability appears to be a result of changes in milk fat, protein, and lactose percentage, with the highest correlation of milk potassium concentration being with milk lactose concentration ($R = -0.53$ or $-0.74$). The relationship between potassium and lactose is attributable to the fact that these are important contributors to milk osmolality, which is constant and isotonic. Milk potassium concentration also changes during lactation, being 42 mmol/L in early lactation, 40 mmol/L in midlactation, and 27 mmol/L in late lactation, with a mean bulk milk potassium concentration of 37 mmol/L. The large cow-to-cow variability in milk potassium concentration and dependence on milk lactose concentration make it difficult to produce a suitable cut-point for identifying whole-body potassium depletion in sick lactating dairy cows. However, milk potassium concentration has clinical utility in monitoring potassium homeostasis over time in an individual cow.

Erythrocyte Potassium Concentration
Erythrocyte potassium concentration is determined by measuring plasma potassium concentration and hematocrit, and then adding sufficient distilled water to hemolyze the erythrocytes followed by potassium measurement of the hemolyzed fluid and mathematical calculation. There is marked cow-to-cow variability in the erythrocyte potassium concentration (7 to 70 mmol/L) and sodium concentration (15 to 87 mmol/L) of healthy cattle that has a genetic basis with no breed influence. There are two main peaks of cellular potassium concentration, one at 20 mmol/L and a second at 50 mmol/L. In lactating dairy cattle with induced whole-body potassium deficiency, whole-blood potassium concentration changed similarly to plasma potassium concentration. However, in 180 cows, no relationship between plasma potassium concentration and erythrocyte potassium concentration was found. Measurement of erythrocyte or whole-blood potassium concentration is not currently recommended in evaluating whole-body potassium status.

Urine Potassium Concentration
Urine potassium concentrations are normally high (454 ± 112 mEq/L) but variable, with a mean fractional clearance of 82% and a coefficient of variation of 61%. The large variability in urine potassium concentration makes it difficult to produce a suitable cut-point for identifying whole-body potassium depletion. However, determination of urine potassium concentration has clinical utility in an individual cow ingesting a constant diet over time because it reflects potassium homeostasis. Urine pH may provide some value as a better screening test because aciduria may be present in response to a marked decrease in urine potassium concentration.

Salivary Potassium Concentration
Salivary potassium concentrations are more influenced by aldosterone in the response to changes in serum sodium concentration, and salivary potassium concentration must therefore be compared with the salivary sodium concentration (one-for-one exchange), sodium homeostasis, and the ratio of serum sodium to potassium to have clinical utility. The normal saliva potassium concentration shows a large range of 4 to 70 mEq/L, with sodium homeostasis having the greatest effect. A study in cattle with left-displaced abomasum, right-displaced abomasum, or abomasal volvulus indicated no association between salivary potassium concentration and serum potassium concentration. Taken together, it appears that measurement of salivary potassium concentration provides minimal insight into whole-body potassium status.

Necropsy Findings
Necropsy of cattle with hypokalemia-induced recumbency reveals the presence of muscle necrosis in the pelvic limbs. Histologic examination of non-weight-bearing muscles reveals multifocal myonecrosis with microphage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in humans and dogs. It is important to note that hypokalemic myopathy is also present in muscles not subject to ischemia of recumbency.

TREATMENT
Treatment of hypokalemia in lactating dairy cows should focus on surgical correction of abomasal displacement, increasing the potassium intake by increasing dry matter intake or the oral administration of KCl, and correction of hypochloremia, alkalalemia, metabolic alkalosis, and dehydration. Oral potassium administration is the method of choice for treating hypokalemia. Inappetent adult cattle should initially be treated with 120 g of KCl PO, followed by an additional oral treatment of 120 g KCl 12 hours later, for a total 24-hour treatment of 240 g KCl (0.4 g/kg BW). Higher oral doses of KCl are not recommended because they can lead to diarrhea, excessive salivation, muscular tremors of the legs, and excitability.

Potassium is rarely administered intravenously; the IV route is used only for the initial treatment of recumbent ruminants with severe hypokalemia and rumen atony because it is much more dangerous and expensive than oral treatment. The most aggressive IV treatment protocol is an isotonic solution of KCl (1.15% KCl), which should be administered at less than 3.2 mL/kg/hr, equivalent to a maximal delivery rate of 0.5 mEq of potassium/kg BW per hour. Higher rates of potassium administration run the risk of inducing hemodynamically important arrhythmias, including ventricular premature complexes that can lead to ventricular fibrillation and death.

Palatable hay and propylene glycol orally are recommended. In a series of 14 cases, treatment consisted of potassium chloride given intravenously and orally at an average total daily dose of 0.42 g/kg BW (26 g orally and 16 g IV) for an average of 5 days, resulting in recovery in 11 cases after an average of 3 days. During recumbency, affected cattle require special attention to minimize ischemic necrosis of muscles of the pelvic limbs.

Glucocorticoids are often used to treat ketosis, and the most commonly used glucocorticoids are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. Dexamethasone is recommended for the treatment of ketosis in dairy cattle at a single dose of 10 to 20 mg IM, and repeated, if necessary, 12 to 24 hours later. Field observations indicate that repeated doses of isoflupredone acetate decrease plasma concentrations of potassium by 70% to 80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone acetate be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required, but treatment may be ineffective.
CONTROL
Oral administration of potassium is a mandatory component of fluid and electrolyte administration to inappetent lactating dairy cattle. Ensuring an adequate dry matter intake is the best method for preventing hypokalemia in lactating dairy cattle.

TREATMENT AND CONTROL

Treatment
KCl 120 g PO, followed by an additional oral treatment of 120 g KCI 12 hours later, for a total 24-hour treatment of 240 g KCI (0.4 g/kg BW) (R-1)
KCI 1.15% IV, less than 3.2 (mL/kg BW)/hour, equivalent to a maximal delivery rate of 0.5 mEq of potassium/kg BW per hour (R-2)
Isoflupredone acetate (R-4)
Control
Maintain adequate dry matter intake (R-1)

DOWNER-COW SYNDROME

SYNOPSIS
Etiology Ischemic myopathy of large muscles of pelvic limbs and ischemic neuropathies of obturator or sciatic nerve or its branches secondary to prolonged recumbency associated with milk fever or dystocia; injury of bones, joints, and muscles; undetermined etiologies.
Epidemiology Most common in dairy cows with previous episodes of milk fever; in beef cows after prolonged or difficult calving. Delay of more than 4 hours in treatment for recumbent milk-fever cows. Hypophosphatemia and/or hypokalemia have been discussed as potential risk factors.
Signs Alert downer cows: Unable to stand following treatment for milk fever. Sternal recumbency; normal mental status, vital signs, and alimentary tract. Appetite and thirst normal or mildly decreased. Most will stand in few days if provided good clinical care and secondary muscle necrosis is minimized.
Nonalert downer cows: Persistent recumbency with alteredmentation and vital signs; frequently unable to maintain sternal recumbency; abnormal position of legs; groaning, anorexia, die in several days.
Clinical pathology Increased serum activity of creatine kinase (CK) and aspartate aminotransferase (AST); serum phosphorus and potassium concentrations may be subnormal or elevated; proteinuria, myoglobinuria.
 Necropsy findings Ischemic necrosis, edema and hemorrhage of large medial thigh muscles.
Diagnostic confirmation Increased serum activities of CK, AST, proteinuria; myoglobinuria necropsy lesions in cow unable to rise with no other lesions.
Treatment Provide excellent bedding or ground surface such as sand or dirt pack. Roll animal from side to side every few hours. Antiinflammatory therapy/pain management. Fluid and electrolyte therapy as necessary. Hoist cows making attempts to stand.
Control All recently calved dairy cows that are at high risk for milk fever must be observed closely 12 to 24 hours before and after calving for evidence of milk fever and while still standing; if recumbent, do not delay treatment for more than 1 hour. Can treat all high-risk cows with calcium salts orally to prevent clinical milk fever.

The term downer cow first appeared in the veterinary literature in the 1950s and referred to cattle that were too injured, weak, or sick to stand or walk without assistance. In most of the early publications using this terminology a case definition was not provided or was imprecise, such as “cattle unable to rise” or “unable to stand without assistance,” and did not make reference to possible etiologies, duration of recumbency, or outcome. More recently the term downer cow was used to denote nonambulatory cattle recumbent for at least 24 hours without obvious reason. A further classification of downer cows into mentally alert, nonambulatory cattle that are able to maintain themselves in sternal recumbency, so-called alert downer cows, and cows with moderate to severe mental obtundation and abnormal vital signs that frequently are unable to maintain sternal recumbency, the so-called nonalert downer cows, was proposed. The term creper cows is sometimes used to denote alert recumbent cows that are unable to bear weight on their hindlimbs but that use the forelegs to propel themselves over short distances.

ETIOLOGY
Alert downer cows are in most cases recumbent because of musculoskeletal or neurologic injuries such as lesions of the sciatic or obturator nerve secondary to dystocia (calving paralysis), fractures of long bones or the pelvis, hip luxation, or muscle injury as a result of primary trauma or secondary to prolonged recumbency. Nonalert downer cows comprise animals with systemic disease affecting mental status and general attitude, such as periparturient hypocalcemia, septicaemia, hypovolemia, diffuse peritonitis, and severe hepatic lipodosis, or neurologic diseases affecting the brainstem or cortex.

In most cases, the downer-cow syndrome is a complication of milk fever. Myopathies and neuropathies develop in nonambulatory cows secondary to prolonged periods of recumbency. Ischemic myopathy affecting the large muscles of the pelvic limbs and injuries to the tissues around the hip joint and of the obturator muscles are common in cows that do not fully recover and stand. Injuries to the musculoskeletal system are also common as a result of cows “spread-eagling” their hindlimbs if they are unsteady during parturition or forced to stand or walk on a slippery floor immediately before or following parturition.

A survey conducted among dairy operations in 21 U.S. states determined that the three most common causes for persistent recumbency were periparturient hypocalcemia (19%), calving-related injuries (22%), and injuries from slipping or falling (15%). Beef cattle operations reported calving paralysis as the single most common cause for downer-cow syndrome.

EPIDEMIOLOGY
Occurrence
The disease is most common in dairy cows and typically occurs within the first 2 or 3 days after calving, often immediately following an episode of milk fever. Other debilitating conditions of periparturient cows that can be associated with persistent recumbency include acute coliform mastitis, septic metritis, and acute rumen acidosis (grain overload).

In the United States an estimated 270,000 cattle became nonambulatory on-farm in 2004, of which 57.4% were dairy and 31.5% beef cattle, corresponding to 1.2% of dairy cattle and 0.2% of beef cattle becoming persistently recumbent in 1 year. An older survey conducted in 1986 in Minnesota that included data from 738 dairy operations and 34,656 cow years at risk reported incidences of 19% and 22%, respectively, and 0.2% of beef cattle becoming persistently recumbent in 1 year.

In the United States an estimated 270,000 cattle became nonambulatory on-farm in 2004, of which 57.4% were dairy and 31.5% beef cattle, corresponding to 1.2% of dairy cattle and 0.2% of beef cattle becoming persistently recumbent in 1 year. An older survey conducted in 1986 in Minnesota that included data from 738 dairy operations and 34,656 cow years at risk reported incidences of 19% and 22%, respectively, and 0.2% of beef cattle becoming persistently recumbent in 1 year.

The overall outcome was that 33% of downer cows recovered, 23% were slaughtered, and 44% died. The owners perceived that downer cows were high producers (48%) or average producers (46%), with only 6% being low producers. Approximately 58% of cases occurred within 1 day of parturition, and 37% occurred during the first 100 days.
of lactation. The incidence was highest (39%) during the three coldest months: December to February. A clinical survey conducted in New Zealand and including 433 periparturient recumbent cows reported a recovery rate of 39%, whereas 30% died, and 32% had to be destroyed. The case-fatality rate in this study was 11% higher in precalving recumbent cows than postcalving cows. A 2006 survey including dairy operations from 21 U.S. states reported that 78.6% of participating operations had at least one downer cow in 2006. The case definition of a downer cow in this study was “nonambulatory cattle that were unable to stand for any length of time, including those that recovered.”

Because it is a syndrome lacking in clinical definition and includes all those “other cases” that cannot be otherwise classified, downer-cow incidence varies depending on the clinical acuity of the individual veterinarian and various environmental factors in different areas. In any case, the incidence seems to be increasing, particularly in intensive dairy farming areas, although this impression could arise from the increased necessity to effect a cure in valuable animals.

**Risk Factors**

**Complication of Milk Fever.** Prolonged recumbency after an episode of clinical milk fever either because of a delay in administration of proper treatment or delayed response to treatment is considered the most common primary cause of downer-cow syndrome. The incidences for downer-cow syndrome that is associated with milk fever reported in the literature range from 3.8% to 28.2% of all milk-fever cases.

Prolonged recumbency, regardless of the primary cause, results in increased tissue pressure over a confined anatomic area, causing local ischemia and neuromuscular dysfunction. An insecure gait of a hypocalcemic periparturient cow presents an increased risk of injury from slipping or falling, such as muscle rupture, bone fractures, or hip luxation, that can result in downer-cow syndrome.

**Traumatic Injuries to Pelvis and Pelvic Limbs.** Traumatic injuries to bones, muscles, and nerves can be directly related to parturition (e.g., calving paralysis), be associated with muscle weakness and an insecure gait (e.g. in hypocalcemic cattle), or be the result of an inadvertent accident. Calving paralysis refers to a paresis or paralysis of one or both hindlimbs caused by a lesion of the obturator nerve and/or the lumbar root of the sciatic nerve inflicted during the calving process. Both nerves are vulnerable to compression between the bony birth canal and the calf at parturition; accordingly, nerve damage is most commonly diagnosed after dystocia, deliveries of large calves, or prolonged calvings. Calving paralysis is considered the most common cause for persistent recumbency in beef cattle.

Pressure injuries of the superficial nerves of the extremities may occur as secondary lesions in cows that are recumbent for an unrelated reason.

**Serum Electrolyte Imbalances.** Apart from hypocalcemia, hypophosphatemia, hypokalemia, and hypomagnesemia have been incriminated as potential factors contributing to downer-cow syndrome. **Hypophosphatemia** is a common finding in recumbent cows but also in healthy periparturient cows; it is the mineral imbalance most commonly quoted as risk factor, especially in the so-called creepier cows, which are bright and alert and crawl about, but are unable to rise. The clinical relevance of hypophosphatemia in persistently recumbent animals has been debated contentiously, but an undisputed empirical observation is that hypophosphatemia is more common or more pronounced in recumbent periparturient cows that are unresponsive to intravenous calcium administration at least in very early stages of recumbency.5,6 However, the mechanisms through which phosphate depletion may cause persistent recumbency are not well understood, and treatment response to oral or parenteral administration of phosphate salts is inconsistent. Studies including cattle that were nonambulatory for longer than just a few hours, in contrast, found that low serum phosphorus levels are suggestive of a good prognosis, whereas nonsurvivors tend to have higher serum phosphorus concentrations. A likely explanation for this finding is that cows recumbent for longer time periods may have developed more severe muscle damage that is associated with release of intracellular phosphorus into the circulation and thus an increase of the serum phosphorus concentration.

A long-term low-level hypomagnesemia has been associated with downer-cow syndrome, especially when it accompanies hypocalcemia. But it is usually manifested by a tetanic hyperesthetic state, which is not part of downer-cow syndrome.

Severe **hypokalemia** in cattle is associated with signs of depression and profound skeletal muscle weakness leading to recumbency. Reports of pronounced hypokalemia in individual animals that were associated with persistent recumbency, with serum potassium concentrations below 2.0 mmol/L, have accumulated over the past decades. These cases have in most instances been traced back to the repeated use of isoupredone, a mineral corticoid with strong kaliuretic effect that was commonly used for the treatment of ketosis in the United States. Mild to moderate hypokalemia is known to occur in early lactating and anorectic cows, but the role of this mild form in the pathogenesis of downer-cow syndrome needs to be determined.8

The **age and stage of lactation** of a recumbent cow were found to be risk factors for nonrecovery. Recovery rates of nonambulatory cows were 10.1% for 1st-lactation cows, 17.7% for cows in their second to fourth lactation, and 22.2% for fifth-lactation cows. Cows less than 15 days in milk had a recovery rate of 28.4%, whereas cows in later lactation had a 6.2% chance of making a full recovery. Higher recovery rates in older cows and cows that were earlier in lactation have been attributed to an association between persistent recumbency and hypocalcemia. Cows that are older and earlier in lactation are more likely to be recumbent because of hypocalcemia as primary or contributing cause, which has a better prognosis than persistent recumbency for other reasons.

**Duration of recumbency** was also found to be associated with the likelihood of making a full recovery. Cows that were down for less than 24 hours recovered in 32% of the cases, whereas cows recumbent for longer periods had an 8.2% chance of recovery.

A high **body-condition score** is a recognized risk factor for milk fever and therefore must also be considered as predisposing for downer-cow syndrome. Cows with a BCS above 4.0/5 around calving were found to be at 4.3 times higher risk to become nonambulatory than thinner cows. In contrast, cows in poor body condition, with a BCS below 2.5/5, recovered in 8.1% of all cases, whereas 16.6% of cows with a BCS of 2.75 or higher made a full recovery.

**Environmental and Management Risk Factors**

A slippery ground surface is a major risk factor. Cattle that must walk across slippery floors, especially at the time of calving, may slip and fall and injure the large muscles of the pelvic limbs, resulting in an inability to stand.

**Pathogenesis**

In most cases downer-cow syndrome is a complication of an unrelated primary problem causing muscle weakness or persistent recumbency. Primary conditions that can lead to downer-cow syndrome have been grouped into four major categories: metabolic disorders (e.g., hypocalcemia, hypokalemia), acute systemic illness (e.g., coliform mastitis, toxic metritis), musculoskeletal disorders (e.g., fractures, joint luxation), and undetermined causes. Prolonged recumbency will result in secondary damage from excessive pressure on limbs squeezed between the body and the ground or from struggling to get up. If severe enough, these secondary lesions may prevent the affected cow from getting up, even though the primary cause of recumbency may in the meantime be resolved. Secondary damage can affect muscles, nerves, or other structural components such as bones or joints. Regardless of the initial cause,
prolonged recumbency results in varying degrees of pressure damage predominantly affecting the hindlimbs. Based on the results of experimental studies, it has been suggested that 6 hours of recumbency is the time threshold, beyond which tissue damage as a result of excessive weight bearing must be expected. This underscores the importance of handling any persistently recumbent cow as a medical emergency.

Pressure damage in recumbent cattle primarily occurs in the major muscles of the hindlimbs, particularly the semitendinous muscle, muscles caudal to the stifle, and the peripheral sciatic nerve and its branches. The local tissue damage is referred to as compartment syndrome; systemic effects resulting from local tissue damage are summarized in the so-called crush syndrome.

Compartment Syndrome
A compartment of the body is composed of muscle and nerves within an anatomically defined area that is surrounded by a rigid muscle fascia layer. In a recumbent cow, the compartments of interest are the ones of the upper part and to a lesser extent the lower part of each hindlimb. The initial pressure acting on the hindlimb located underneath the body of a recumbent cow depends on the body weight resting on this limb and the rigidity of the ground on which the cow is lying. This pressure on the limb directly translates into increased pressure within the affected compartment and will result in partial or complete occlusion of venous blood flow before the arterial blood flow of the affected region is decreased. The mismatch between blood flow into and out of the compartment leads to a further pressure increase within the compartment. Impaired blood supply to muscles and nerves and ensuing tissue hypoxia will add to the direct damage from mechanical compression. The thick muscle-fascial boundaries surrounding the compartment prevent tissue expansion that would relieve the structures within the compartment from the excessive pressure. Cell damage and inflammation are associated with swelling, causing a further increase in pressure and contributing to a detrimental cascade of events.

Experimental external compression of the pelvic limb in goats, to simulate limb compression in recumbent cows, resulted in a marked reduction in the nerve conduction velocity of the peroneal nerve, which was associated with clinically evident limb dysfunction.

Crush Syndrome
Crush syndrome refers to the sum of the systemic effects of extensive muscle tissue injury and is attributed to the massive release of muscle-tissue breakdown products into the blood circulation. Notably, a large increase in the serum activity of muscle enzymes, such as aspartate aminotransferase (AST) or creatine kinase (CK); increases in serum concentration of predominantly intracellular electrolytes, such as potassium and phosphorus; and ultimately the appearance of myoglobin in urine are indicative of crush syndrome. Myoglobinuria is a potentially life-threatening complication of downer-cow syndrome that can lead to acute renal failure.

Experimental Sternal Recumbency
Experimentally induced sternal recumbency with one hindlimb positioned under the body to simulate prolonged recumbency will result in a swollen rigid limb within 6 to 9 hours. Following injury to the muscle cells, the serum activity of CK is markedly elevated at about 12 hours after the onset of recumbency. Proteinuria and in some severe cases myoglobinuria occur between 12 and 36 hours after the onset of prolonged recumbency, as a result the release of myoglobin from damaged muscles. In cows that make efforts to stand but cannot do so, continued struggling may result in rupture of muscle fibers and hemorrhage.

Acute focal myocarditis occurs in about 10% of cases, resulting in tachycardia, arrhythmia, and the unfavorable response to IV calcium salts observed in some cases. The cause of the myocardial lesion is unknown, but repeated administration of calcium salts has been suggested. The prolonged recumbency can result in additional complications, such as acute mastitis, decubitus ulcers, and traumatic injuries of the limbs.

The pathogenesis of the nonalert downer cow is not understood. Most such cows have had an initial episode of milk fever and did not respond satisfactorily. Within 1 or 2 days, affected cows have a preference for lateral recumbency and exhibit expiratory moaning and groaning. They represent about 2% of all cases of milk fever.

CLINICAL FINDINGS
Downer-cow syndrome may occur independently or follow apparent recovery after treatment for milk fever, except for the prolonged recumbency. In the typical case, affected cows either make no effort or are unable to stand following treatment for par-turient paresis. About 30% of cows treated for milk fever will not stand for up to 24 hours following treatment. Affected cows are usually bright and alert with good or only mildly depressed feed intake and are thus classified as alert downer cows. The temperature is normal and the heart rate may be normal or elevated to 80 to 100 bpm. Tachycardia and arrhythmia occur in some cows, especially immediately following the administration of IV calcium, and sudden death has occurred. Respirations are usually unaffected. Defecation and urination are normal, but proteinuria is common and may indicate extensive muscle damage if marked.

Some affected cows may make no effort to stand. Others will make frequent attempts to stand but are unable to fully extend their pelvic limbs and lift their hindquarters more than 20 to 30 cm from the ground. On a nonslippery surface (bare ground, sand pack, or deep bedding) some cows are able to stand with some assistance by lifting on the tailhead or with the use of hip slings. Those cows that do not make an effort to stand usually cannot stand even with assistance, and if supported with cow slings, they will usually make no effort to bear weight with either the hindlimbs or the forelimbs. Their limbs appear stiff, painful, or numb, and they are unable or reluctant to bear weight. Damage to the peroneal nerve is usually present when there is hyperflexion of the fetlock joints, which is evident if and when the cow is able to stand and bear weight on the hindlimbs.

In some cases, the hindlimbs are extended on each side of the cow and reach up to the elbows on each side. In this position, the cow is bearing considerable weight on the medial thigh musculature and causing ischemic myopathy. This abnormal position of the legs may also result from dislocation of one or both hip joints or be associated with traumatic injuries surrounding the hip joints with or without rupture of the ligamentum teres. Regardless of the cause, the cow prefers this leg position and invariably will shift the legs back to the abnormal position if they are placed in their normal position.

In some cows, the signs may be more marked and bizarre, including a tendency to lie in lateral recumbency with the head drawn back. When placed and propped up in sternal recumbency, these cows appear almost normal, but when they are left alone, they revert to the position of lateral recumbency. These severe cases do not usually eat or drink and have been described as nonalert downers.

Complications in downer-cow syndrome are common and often result in death or the need for euthanasia. Coliform mastitis, decubitus ulceration, especially over the prominences of the hock and elbow joint, and traumatic injuries around the tuber coxae caused by the hip slings are common. When these complications occur in the early stages of the disease, they commonly interfere with any progress being made and become the focus of clinical attention.

The course of the disease is variable and dependent on the nature and extent of the lesions and the quality of the care and comfort that is provided for the cow during the first few days. About 50% of downer cows will stand within 4 days or less if cared for properly. The prognosis is poor for those that are still recumbent after 7 days, although some affected cows have been down for 10 to 14 days and subsequently stood up and recovered. Death may occur in 48 to 72
hours following the onset and is usually associated with myocarditis.

**Clinical Examination of the Downer Cow**

Clinical examination of the downer cow can be very difficult and challenging depending on the environmental circumstances and the physical size of the animal. Causes of persistent recumbency in cattle include metabolic, musculoskeletal, neurologic, neoplastic, and inflammatory disease; accordingly, obtaining an adequate history and conducting a thorough physical examination are indispensable. Key aspects of the history include age and stage of lactation of the animal, duration of recumbency, any previous clinical abnormalities before the recumbent stage, any previous treatments, diet and accidental access to new feeds, sudden uncustomed exercise, and assessment of the management provided.

The environment and the ground surface surrounding the recumbent animal may provide clues about the possibility that the animal slipped, fell, and was injured.

A systematic physical examination of all accessible body systems is necessary. The animal should be examined visually from a distance for evidence of abnormalities of the carriage of the head and neck, to observe the position of the limbs, and to observe any attempts of the animal to stand or creep along the ground surface.

The details of the clinical examination are presented elsewhere in this book. The standard close clinical examination is necessary to determine body temperature, heart rate and pulse, respiratory rate, and the state of the major body systems, such as the respiratory tract, cardiovascular system, central nervous system for mental state, gastrointestinal tract, mammary gland, and reproductive tract, any of which may indicate the presence of abnormalities associated with shock that results in recumbency.

In the recently calved cow, particular emphasis must be given to adequate examination of the udder for mastitis, the uterus for metritis, and the gastrointestinal tract for diseases associated with toxemia, dehydration, and shock (abomasal volvulus, acute diffuse peritonitis, carbohydrate engagement) that result in recumbency. A urine sample must always be obtained and tested for ketones and the presence of myoglobinuria. Careful systematic examination of the musculoskeletal system includes palpating the muscles, bones, joints, and feet of each limb, including passive flexion and extension of each limb. The coxofemoral joints are examined for evidence of dislocation. The vertebral column is examined for evidence of fracture or dislocation of vertebrae. It is important to examine both sides of the animal, which means rolling the cow over from side to side; often the animal may have to be rolled over more than once to repeat a particular examination.

A neurologic examination includes examination of the withdrawal reflexes, patellar reflexes, and sensation of all four limbs and the reflex arcs of the spinal cord; careful examination of lumbar and sacral areas, including sensation and tone in the tail; and examination of the cranial nerves.

The examination can be extended by lifting the downer cow with appropriate lifters and observing if the animal extends its limbs and attempts to bear weight. While the animal is being assisted to stand, additional examinations of other parts of the body can be made.

**CLINICAL PATHOLOGY**

The serum calcium and glucose concentrations are frequently within the normal range, whereas phosphorus and potassium concentrations may be decreased in cows with depressed feed intake or increased in animals with more pronounced muscle damage and/or dehydration. Results of hematologic examinations are usually unremarkable in early stages of the recumbency. The serum activity of CK and AST are usually markedly elevated by 18 to 24 hours after the onset of recumbency. Very high levels of serum CK activity shortly after the onset of recumbency that decline markedly within the following 24 to 48 hours are indicative of an acute muscle trauma (e.g., muscle rupture) that may be the cause of recumbency. More moderate elevation of the serum activity of CK with a tendency to slightly increase or remain constant over the following days is suggestive of continuous and ongoing muscle trauma resulting from prolonged muscle-tissue compression. Muscle tissue is rich in CK, and the plasma half-life of this enzyme in cattle is only about 8 to 9 hours; this parameter is therefore a sensitive but short-lived marker of muscle damage. When interpreting the serum CK activity of a recumbent cow, it is critical to consider the time of sample collection relative to onset of recumbency.

AST, in contrast, has a considerably longer half-life and remains elevated for several days after initial trauma. In a series of 262 recumbent dairy cows, serum samples were analyzed for CK, lactate dehydrogenase (LDH), and AST to evaluate the value of serum enzyme activities for predicting a failure to recover. The optimal cutoff points maximizing the sensitivity and specificity of the tests were 2330, 2225, and 171 U/L for CK, LDH, and AST, respectively. The predictive value of AST was significantly better, with optimal cutoff points of 128 and 189 U/L, respectively. AST provided the best predictive indicator of whether a recumbent cow would not recover, the best results being obtained with serum samples taken on the first day of recumbency.

In experimentally induced recumbency in cows, the CK activity remained within normal limits for the first 6 hours. However, by 12 hours there was a marked increase to mean values of 12,000 U/L rising to 40,000 U/L by 24 hours. There may be moderate ketonuria. A marked proteinuria is usually evident by 18 to 24 hours after the onset of recumbency. The proteinuria may persist for several days or be absent within a few days. In severe cases, the urine may be brown and turbid because of severe myoglobinuria.

Elevations of serum urea, muscle enzymes, and laboratory evidence of inflammation are considered the best prognostic indicators of an unfavorable recovery. The recovery rate was lower in cows with a total protein : fibrinogen ratio less than 10:1, and evidence of neutropenia and/or left shift. Cows with a serum urea level above 25 mmol/L and serum creatinine levels above 130 mmol/L had a poor prognosis.

**NECROPSY FINDINGS**

Hemorrhages and edema of the skin of traumatic origin are common. The major pathologic changes consist of hemorrhages and degeneration of the medial thigh muscles. Hemorrhages around the hip joint with or without rupture of the ligamentum teres are also common. Local areas of ischemic necrosis of the musculature (gracilis, pectineus, and adductor muscles) occur at the anterior edge of the pelvic symphysis. Eosinophilic infiltration of ruptured necrotic thigh muscles of downer cows has been described. Hemorrhages and edema of the nerves of the limbs (obturator, sciatic, peroneal, radial) are also common and usually associated with severe muscle damage. The heart is dilated and flabby; histologically, there is focal mycarditis. There is fatty degeneration of the liver, and the adrenal glands are enlarged. Histologically, there are also degenerative changes in the glomerular and tubular epithelium of the kidneys.

**DIFFERENTIAL DIAGNOSIS**

The diagnosis of downer-cow syndrome is typically made by exclusion of all other known causes of recumbency in a cow persistently recumbent for at least 24 hours while having received two courses of parenteral calcium treatment.

**Differential diagnoses for alert downer cows:**

- Hypocalcemia
- Calving paralysis
- Fractures of bone or pelvis
- Hip luxation
- Hypokalemia
- Botulism
- Spinal lymphosarcoma (BLV)

**Differential diagnoses for nonalert downer cows:**

- Hypocalcemia
- Hepatic lipidosis/puerperal liver coma
- Coliform mastitis
- Toxic metritis
TREATMENT

Treatment of a nonambulatory cow evidently must focus on the primary cause of recumbency whenever it has been identified, but must also address secondary damage resulting from prolonged recumbency. The reader is referred to the corresponding chapter of this book for the treatment of primary cause of recumbency whenever it is known. Intensive supportive care is required for the treatment of secondary damage and prevention of further damage. The prognosis of a downer cow not only depends on the initial cause of the recumbency but to a large part also on the quality of the care provided during the recumbent period.

Antiinflammatory Therapy

Antiinflammatory therapy as part of pain management in ruminant production medicine has received increased attention over the past years because this is increasingly recognized as an essential aspect of animal welfare by veterinarians and owners alike. Although currently not much data are available to support the use of steroidal and nonsteroidal antiinflammatory drugs in downer cows, their use seems indicated not only to alleviate pain and discomfort of the sick, nonambulatory cow, but also to contain and control inflammation secondary to recumbency that is likely to exacerbate myopathy and neuropathy. Pain in cattle, as in other species, can occur as result of tissue damage, nerve damage, and inflammation, all factors considered to greatly contribute to downer-cow syndrome.

Repeated doses of nonsteroidal antiinflammatory drugs (NSAIDs) may be required for adequate control of pain and inflammation, which may put the treated animal at increased risk for adverse gastrointestinal effects, such as abomasal ulceration. It is therefore advisable to instruct the patient owner to regularly check the produced feces for signs of melena.

A single but high dose of dexamethasone (0.2 to 0.3 mg/kg IV) early in the recumbent period has been advocated by some clinicians, based on clinical experience, to control and contain inflammatory neuropathy resulting from trauma or pressure. Because of the abortive effect of the treatment, this therapy in pregnant cows must be discussed with the animal owner.

Fluid and Electrolyte Therapy

Fluid and electrolyte therapy orally and if necessary parenterally is indicated in patients with inadequate water and feed intake. Multiple electrolytes can be added to the drinking water if the cow is drinking normally. The supplementation of minerals such as phosphates, magnesium, or potassium has been advocated, but they have been used without consistent success.

Oral fluid therapy by drenching is an effective way to maintain hydration in an alert animal. For a recumbent cow, drenching should only be considered in alert cows with a good swallowing reflex. Because the pressure on visceral organs is increased with recumbency, the amount of fluid administered per treatment should not exceed 40 L to prevent the risk of reflux as a result of increased intraruminal pressure.

Bedding and Clinical Care

The most important aspect of treatment is to provide the most comfortable bedding possible and to roll the cow from side to side several times daily to minimize the extent of ischemic damage and para-analgesia that results from prolonged recumbency. With conscientious care and the provision of good bedding, palatable feed, and liberal quantities of water, most cows will attempt to stand with some difficulty and assistance within 24 hours, and most will stand unassisted and normally 1 or 2 days later. A sand or dirt pack is the ideal ground surface to facilitate standing when downer cows attempt to stand. If affected cows are left on a slippery ground surface, they will not make an effort to stand and will become progressively worse. Cows should be milked normally and the udder kept clean by washing with germicide soap before milking, and postmilking teat dips should be applied.

Assisted Lifting to Aid Standing

The clinician and farmer are commonly faced with the questions of whether or not to lift a recumbent cow that has not attempted to stand within a few hours after treatment for milk fever. The guiding principle should be the behavior of the cow. If the cow makes an effort to stand on her own or by some coaxing such as a gentle nudge in the ribs, she should be assisted to stand by ensuring a good nonslip ground surface, providing deep bedding, and lifting up on the tailhead when she attempts to stand. The cow should be rolled from side to side every few hours and encouraged to stand a few times daily.

Several different kinds of cow-lifting devices have been used to assist downer cows to stand. Hip lifters, which fit and tighten over the tuber coxae, and body slings such as harnesses are designed to fit around the abdomen and thorax of the animal. These devices can assist a downer cow to stand if she makes some effort on her own. For those cows that make some effort to stand, the hip lifters or slings can be applied and the animal lifted to the standing position. If the animal bears weight on all four legs, she should be allowed to stand with the aid of the device for 20 to 30 minutes and then lowered down. This procedure can be repeated once or twice a day, provided the cow is able to support her own weight while standing. In most cases, such downer cows will stand on their own within a few days. While the cow is in the standing position, she can be milked, and other clinical examinations can be carried out.

The hip lifters can result in traumatic injuries to the tissues surrounding the tuber coxae if not used judiciously. Cows carrying their own weight after being lifted must not under any circumstances be left unattended while hoisted with the hip lifter because they could lose strength and hang in the device, which could result in severe trauma. Animals that make no effort to stand and bear weight on their own must not be left suspended in the lifter for more than a few minutes but lowered immediately. If the hip lifters are not applied carefully, the animal may slip out of the device while it is being lifted, which commonly results in tissue injury around the tuber coxae; fractures of the coxae have even occurred. These injuries are often unnoticed clinically, but contribute to persistent recumbency. Lifting devices must be used carefully by experienced personnel.

Body slings that fit around the abdomen and thorax of the animal are more suitable to lift down cows that will not readily bear weight after being hoisted, because they distribute the weight over several sites in contrast to the hip lifters, which concentrate the weight over the tuber coxae. However, the body slings are cumbersome to apply to a recumbent animal, and they require more time and experienced personnel to ensure proper application. When the slings are applied properly, they do appear to allow the lifted animal to stand comfortably for 30 minutes or more and promote recovery.

Lifting cows that make no effort to stand on their own is usually unsuccessful. When lifted, they usually do not bear any significant weight.

More recently, water flotation tanks have been used for the management of nonambulatory cows. Proposed devices consist of a watertight metal tub with inside dimensions of approximately 234 cm long, 109 cm wide, and 130 cm high. The system can be mobile, and although the use is labor intensive, it can give good results when selecting suitable patients judiciously. Depending on the system used the downer cow is either pulled into the tub on a mat and the ends of the tub closed to make a water-tight container with an open top like a bathtub or it is fitted with a harness and lifted into the tub already filled with warm water. With the cow’s head held up by a halter, the tub is filled with water at 37° to 38°C (100°F to 102°F) as quickly as
possible. Cows in lateral recumbency will roll into sternal recumbency when 40 to 45°C (104°F), more hot water is added. Cows are allowed to stand in the water for 6 to 8 hours, in some cases up to 24 hours. If the water temperature falls below 35°C (95°F), more hot water is added.

Cows with ruptured tendons, fractures, luxated coxofemoral joints, septic polyarthritis, and other physical injuries of the musculoskeletal system are not good candidates for flotation. The most suitable case for flotation would appear to be the downer cow as a sequel to milk fever.

**Handling, Transportation, and Disposition of Nonambulatory Cattle**

There has been considerable controversy and disparity among veterinarians and livestock producers about the handling, transportation, and disposition of nonambulatory cattle. Economics has a major influence on decision making in these cases. There has been no common understanding of whether or not they are fit for transportation and which ones are fit for slaughter for salvage. When the owner and veterinarian are faced with a downer cow that is valuable and the cause of the recumbency is uncertain, the tendency is to either attempt to provide treatment for several days and assess the progress or consider slaughter for salvage. In the case of valuable breeding animals that are recumbent as a complication of milk fever, or a disease such as acute carbohydrate engorgement or peracute mastitis, supportive and specific therapies are commonly selected. In the case of downer cattle of commercial value, slaughter for salvage has been a common option. Cattle producers would like to obtain as much financial return as possible by slaughter for salvage. Cattle affected with complications of milk fever, traumatic injuries of the musculoskeletal system, and other diseases not associated with toxemia or septicemia are commonly submitted to slaughter for salvage. Transportation of these compromised animals has always been an animal welfare issue because of the difficulty of loading them humanely because of their size. The mere act of lifting, pulling, dragging, or by other means forcefully loading an animal weighing 500 to 800 kg onto a truck cannot be done without considerable pain and discomfort to the animal. However, beginning in the 1990s, worldwide concern emerged from the public about the handling and disposition of nonambulatory animals, particularly downer cows, regardless of the cause of their recumbency. Government animal health regulatory agencies, livestock associations, and veterinary associations began drafting regulations on the care and handling of nonambulatory recumbent animals such as the downer cow.

Downer-cow syndrome is an animal welfare issue, and the veterinarian should be proactive about the problem. Society is concerned about how downer animals are cared for and handled and the methods used for their disposition. If recovery does not occur within a few days, the prognosis is uncertain; the owner and veterinarian must decide whether to continue providing clinical care to the downer cow or whether the animal should be euthanized.

**Euthanasia**

The quality of care provided to a recumbent cow can easily become an issue of animal welfare, and humane euthanasia should always be considered, particularly in cases with poor prognosis or when the attending veterinarian can foresee that adequate supportive care cannot or will not be provided for whatever reason. Suggested “trigger points” for euthanasia suggested in the literature include the following: 10

- Conditions with poor prognosis
- Pain and suffering that is unresponsive to treatment
- Anorexia over several days
- Nonalert downer cows not responding to treatment in due time
- Cows unable to maintain sternal recumbency
- Owner unable or unwilling to provide adequate care
- Complications such as pressure sore, mastitis, or other condition
- Deterioration despite adequate patient care
- Unresponsive to treatment for over 10 days

**TREATMENT AND CONTROL**

**Supportive care**

- Move cow off concrete floor onto soft bedding (R-1)
- Oral fluid therapy in dehydrated or anorectic cows (R-1)
- Roll recumbent cow from one side to the other q4-8h (R-1)
- NSAIDs (at label dose with label treatment interval) (R-2)
- Dexamethasone (0.2 to 0.3 mg/kg IV as a single dose) (R-2)
- Hoist cows that make attempts to stand (R-2)

**Control**

- Close monitoring of periparturient cows for signs of milk fever (R-1)

**REFERENCES**

**CONTROL**

The early detection and treatment of milk fever will reduce the incidence and severity of downer-cow syndrome. Under ideal conditions, cows should be treated during the first stage of milk fever before they become recumbent. Once recumbent, cows should be treated as soon as possible and not delayed for more than 1 hour. Cows with milk fever should be well bedded with liberal quantities of straw or moved to a soft-ground surface. Recumbent cows should be coaxed and assisted to stand if possible after treatment for milk fever. If they are unable to stand, they should be rolled from one side to the other every few hours if possible. It is usually difficult to get owners to comply with this recommendation, but frequent rolling from side to side is necessary to minimize the ischemic narcotics. Dairy cows should be placed in a comfortable, well bedded box stall before calving and should be left in that box stall until at least 48 hours after partition in the event that milk fever develops.

The renal threshold for magnesium absorption

**WHEAT PASTURE POISONING**

Tetany, Grass Staggers, Lactation Tetany, Grass Hypomagnesemic Tetany

may predispose to hypocalcemia. A cause of subclinical tetany, without manifestations of tetany, can be seen in cattle. A chronic hypomagnesemia of sheep, although less common, occurs in the same general groups of circumstances as the disease in cattle. A chronic hypomagnesemia, without manifestations of tetany, can be a cause of suboptimal production efficiency and may predispose to hypocalcemia.

**HYPOMAGNESEMIC TETANIES**

Tetany associated with a marked decrease in serum magnesium concentration is a common occurrence in ruminants. The syndrome associated with hypomagnesemia is relatively constant, irrespective of the cause, but the group of diseases in which it occurs has been divided into three groups:

- hypomagnesemic tetany of calves, which appears to result specifically from a deficiency of magnesium in the diet to transport tetany
- a group of hypomagnesemias in ruminants characterized by lactation tetany, in which there may be a partial dietary deficiency of magnesium but in which nutritional or metabolic factors reduce the availability, or increase the body's loss, of the element so that serum magnesium levels fall below a critical point.

In general, the occurrence of hypomagnesemic tetany is related to three sets of circumstances. Most common is the occurrence in lactating cows turned out onto lush, grass-dominant pasture in the spring after wintering in closed housing— the classic lactation or grass tetany of England. Wheat pasture poisoning may occur when cattle or sheep are grazed on young, green cereal crops. The third occurrence is in beef or dairy cattle running at pasture in the winter, usually when nutrition is inadequate and where no shelter is provided. Hypomagnesemia of sheep, although less common, occurs in the same general groups of circumstances as the disease in cattle. A chronic hypomagnesemia, without manifestations of tetany, can be a cause of suboptimal production efficiency and may predispose to hypocalcemia.

**HYPOMAGNESEMIC TETANY (LACTATION TETANY, GRASS TETANY, GRASS STAGGERS, WHEAT PASTURE POISONING)**

**SYNOPSIS**

Etiology The etiology is multifactorial, related to magnesium concentration in the diet and the presence of competing cations such as potassium and sodium that affect either herbage magnesium status or magnesium absorption.

**Epidemiology**

Disease of all classes of ruminants, but reaches its highest incidence in older lactating cows exposed to bad weather or grazing green cereal crops or lush grass-dominant pasture.

**Clinical findings**

Incoordination, hyperesthesia and tetany, tonic-clonic muscular spasms and convulsions. High case fatality without treatment.

**Clinical pathology**

Serum, urine, vitreous humor, or cerebrospinal fluid (CSF) magnesium concentrations. Hypomagnesemia, and in some circumstances hypocalcemia.

**Necropsy findings**

None specific.

**Diagnostic confirmation**

Response to treatment, serum or urinary magnesium concentrations.

**Treatment**

Magnesium or combined calcium/magnesium solutions administered IV or SC.

**Control**

Magnesium supplementation, but a palatable and practical delivery method is a problem. Magnesium applied to pastures. Avoidance of movement and food deprivation at risk periods.

**ETIOLOGY**

Magnesium is the major intracellular divalent cation and is an essential element in a large number of enzymatic activities in the body. For this reason, it might be expected that hypomagnesemia would be rare. However, because of the peculiarities of absorption of magnesium in the ruminant forestomach, and the use of animal and pasture management systems that can lead to marginal magnesium uptake, ruminants are at risk of hypomagnesemia.

**Magnesium Homeostasis**

There is no feedback regulatory mechanism to control concentrations of magnesium in the body of ruminants. As a consequence, magnesium concentrations in blood and extracellular fluid are essentially determined by the balance between dietary intake of magnesium, loss in feces and milk, and the modulating effect of magnesium homeostasis by the kidney.

**Dietary Intake**

In normal circumstances, magnesium absorbed from the diet is sufficient to meet the requirements of the body, and excess amounts are excreted in the urine.

**Renal Excretion**

The kidney is the major organ of homeostasis and can act to conserve magnesium. Magnesium is freely filtered across the renal glomerulus and is reabsorbed within the renal tubules, the degree of reabsorption acting in homeostasis. The endogenous daily urinary loss is typically 3 mg/kg BW, equivalent to 1.8 g/day for a 600-kg cow. When the dietary intake of magnesium is decreased, blood and interstitial fluid magnesium concentrations fall; excretion of magnesium in the urine will cease when serum concentrations fall below 1.8 mg/dL. The renal threshold for magnesium excretion is partially under the control of parathyroid hormone, and increased plasma concentrations of parathyroid hormone will act to conserve magnesium.

**Magnesium Reserves**

There are large stores of magnesium in the body, especially in bone. These are available to the young calf, but mobilization rate decreases with age, and in the adult ruminant there is little mobilization in response to short-term deficits of magnesium. In ruminants, this control mechanism for magnesium can maintain adequate concentrations of magnesium in bodily fluids in most production circumstances, but it can fail where there is a high requirement for magnesium coupled with a decreased intake. This combination leads to hypomagnesemia, and hypomagnesemic tetany is a possible outcome.

**Lactation**

Increased requirement for magnesium is almost always associated with the loss of magnesium in the milk during lactation. Whereas the amount of magnesium in milk is not high (14 mg/kg BW), the loss of magnesium to milk in high-producing animals (4.2 g of magnesium in 30 L of milk) represents a significant proportion of the dietary intake of magnesium. As a consequence of this drain, most instances of hypomagnesemia occur in lactating animals around the period of peak milk production, although in some circumstances the demands of late pregnancy are the cause of the increased requirement. The decreased intake of magnesium can result from an absolute deficiency of magnesium in the diet or because the availability or absorption of magnesium from the diet is impaired. These factors determine the circumstances of occurrence of the disease and are the factors that can be manipulated for control.

**Factors Influencing Absorption of Magnesium**

In the adult ruminant, magnesium absorption occurs in the forestomach with little absorption in the abomasum and small intestine. Some absorption occurs in the large intestine, particularly in sheep; however, it cannot compensate for malabsorption in the forestomach. Magnesium is absorbed from the small intestine of calves, lambs, and kids, but this ability appears to be lost when these animals become ruminants.

**Na:K Ratio in Rumen**

Magnesium is transported across the epithelium of the forestomach by an active sodium-linked ATPase-dependent transport system. Absorption, and the serum magnesium concentration, is influenced by the...
Na:K ratio in the rumen, which is determined by the dietary and salivary concentrations of sodium and potassium. Absorption of magnesium increases with an increasing Na:K ratio to plateau at a ratio of 5:1. Absorption is significantly impaired if the Na:K ratio is less than 3:1.

Young, rapidly growing grass that is low in sodium and high in potassium can result in sodium deficiency in grazing ruminants and can significantly depress the Na:K ratio in the rumen fluid, causing impaired magnesium absorption. Depression is observed at dietary potassium concentrations of greater than 22 g/kg dry matter.

Saliva normally has a high Na:K ratio, but where there is a deficit of sodium in the diet, a proportion of sodium in saliva may be replaced with potassium under the influence of aldosterone, which further negatively influences the uptake of magnesium. Approximately 40% of the total magnesium available in extracellular fluid is secreted daily in saliva, and 20% of this is reabsorbed in the forestomach. When animals are on tetany-prone grass, forestomach absorption is impaired, which accounts for the susceptibility of ruminants to hypomagnesemia compared with monogastric animals.

Other Factors Influencing Absorption

Young grass fertilized with nitrogenous fertilizers has an increased crude protein content, which is readily fermentable and leads to increased ammonia concentrations. A sudden rise in ruminal concentrations of ammonia impairs magnesium absorption in the rumen. The uptake of magnesium is also influenced by the carbohydrate content of the diet; magnesium absorption is improved with increasing amounts of readily degradable carbohydrates. The mechanism of this action is not known, but low concentrations of readily degradable carbohydrate in tetany-prone pastures in combination with high concentrations of protein may be important to the occurrence of the syndrome. Volatile fatty acids provide the energy for the active transport of magnesium across the rumen wall and increase magnesium absorption.

Ruminal pH is thought to affect absorption efficiency by influencing magnesium solubility, which decreases markedly as ruminal pH increases above 6.5. Magnesium binders, such as fats, can form insoluble magnesium salts. Other dietary substances have been proposed to influence the absorption of magnesium, including calcium and phosphorus, organic acids such as citric acid and transacconitate, fatty acids, and aluminum, but the significance of their role is controversial.

**Magnesium in Pastures and Tetany Hazard**

The dietary intake of magnesium in grazing animals is directly related to the magnesium concentration in pastures, but other elements in pastures also influence magnesium absorption by the ruminant, as detailed earlier.

**Required Magnesium Concentrations**

Hypomagnesemia can result from the ingestion of pastures that have insufficient magnesium to meet dietary requirements. The estimated magnesium concentration in pasture required to meet the dietary requirement for pregnant or lactating cattle varies from 1.0 to 1.3 g/kg dry matter (DM) for pregnant cattle, depending on the stage of pregnancy, and from 1.8 to 2.2 g/kg DM for lactating cattle, with both estimates assuming minimal interference of absorption by other elements in the pasture.

The recommended minimal “safe” concentration of magnesium in pastures is 2 g/kg DM for lactating and pregnant cattle, with a preference for a concentration of 2.5 g/kg DM.

**Magnesium Availability in Pastures and Hazard**

Hypomagnesemia can also occur in animals grazing pastures with adequate concentrations of magnesium but that contain high concentrations of potassium and nitrogen, which, as detailed earlier, impairs absorption of magnesium in the rumen. Pastures with concentrations of potassium of greater than 30 g/kg DM and nitrogen greater than 40 g N/kg dry matter are considered hazardous.

An alternate method for estimating the potential hazard of a pasture is to calculate the K/(Ca + Mg) ratio using milliequivalent (mEq) values for this estimate. Pastures with ratios above 2.2 are considered a risk.

**Winter Hypomagnesemia**

The occurrence of hypomagnesemia is not restricted to cattle grazing lush pastures; it can also occur during winter. In housed lactating dairy cattle being fed conserved feeds, hypomagnesemia probably has the same genesis as that in grazing cattle, being associated with a high lactational demand of magnesium in combination with the feeding of conserved feeds prepared from pastures with marginal magnesium concentrations. Hypomagnesemia also occurs in cattle outwintered on poor-quality feed.

**Hypomagnesemia and Hypocalcemia**

In some outbreaks of hypomagnesemic tetany, there is also hypocalcemia, and although it is of less severe degree than in parturient paresis, there is increasing evidence that the actual onset of clinical tetany may be associated with a rapid fall in serum calcium levels superimposed on a preexisting hypomagnesemia. This is particularly true for wheat pasture poisoning but can also apply to outbreaks with different predisposing factors.

Chronic hypomagnesemia can have a profound effect on calcium homeostasis. Hypomagnesemia reduces the production and secretion of parathyroid hormone, reduces hydroxylation of vitamin D in the liver, and also causes target-organ insensitivity to the physiologic effects of parathyroid hormone and 1,25-dihydroxyvitamin D₃. Chronic subclinical hypomagnesemia can increase susceptibility to milk fever and can predispose to episodes of milk fever and downer cows in lactating dairy cows during the period of peak lactation.

**Summary of Etiology**

In summary, it appears that a number of factors are capable of causing hypomagnesemia in ruminants and that under particular circumstances one or other of them may be of major importance.

In lactation tetany of cows and ewes turned out onto lush pasture in the spring, a primary dietary deficiency of magnesium or the presence of high relative concentrations of potassium and nitrogen in the diet reduces the absorption of magnesium and possibly calcium.

In wheat (cereal) pasture poisoning, the ingestion of abnormally large amounts of potassium and low levels of calcium in the diet leads to hypomagnesemia and also hypocalcemia.

**Hypomagnesemic tetany in cattle wintered at pasture** and exposed to inclement weather is associated with low magnesium intake and inadequate caloric intake, and possibly to the resultant hyperactivity of the thyroid gland.

Although the suggestions as to the most important etiologic factors in each set of circumstances in which lactation tetany occurs may be valid, undoubtedly combinations of these and other factors have etiologic significance in individual outbreaks of the disease. The worst combination of causative factors, and the most common circumstances in which the disease occurs, is inadequate energy intake with a low dietary content of magnesium (grass pasture) in recently calved cows during a spell of cold, wet, and especially windy weather.

One other important factor is the variation between individual animals in susceptibility to hypomagnesemia and to the clinical disease. These variations are quite marked in cattle, and in intensively managed, high-producing herds it is probably worthwhile to identify susceptible animals and give them special treatment.

**Epidemiology**

**Occurrence and Risk Factors for Lactation Tetany**

Lactation tetany in dairy and beef cattle turned out to graze on lush, grass-dominant pasture after winter housing is common in northern Europe, the United Kingdom, and the northern parts of North America. Grass tetany also occurs in Australia and New Zealand, where the cows are not housed in winter but have access to a phenomenal flush.
of pasture growth in the spring. This also commonly occurs in beef cattle in all countries.

With housed cattle, or cattle fed conserved feed during the winter, most cases occur during the first 2 weeks after the cattle are turned out to spring pasture. Pasture that has been heavily top dressed with fertilizers rich in nitrogen and potash is potentially the most dangerous. The disease may also occur on this type of pasture even when the cattle have wintered on pasture in temperate regions. In regions where there is an autumn flush of pasture, a high incidence of hypomagnesemic tetany may occur in the autumn or early winter.

Cattle in the first 2 months of lactation and 4 to 7 years of age are most susceptible, which probably reflects an increased risk because of a higher loss of magnesium in milk. Friesian cows have lower magnesium concentrations than Jerseys grazed under the same conditions.

In the northern parts of the United States, outbreaks commonly occur during periods of low barometric pressure when the ambient temperature ranges between 7°C (45°F) and 16°C (60°F) and soil temperatures are below 7°C (45°F). Outbreaks may be precipitated by inclement weather. In beef cattle there is a history of poor nutrition and falling body condition in the past few weeks as a result of diminishing hay supplies.

Occurrence and Risk Factors for Wheat (Cereal) Pasture Poisoning
Wheat pasture poisoning is a misnomer because it can occur with grazing of any small-grain cereal pasture. It has been recorded in many countries, but it is most prevalent where young cereal crops are utilized for winter grazing. The southwestern United States has experienced heavy losses of cattle caused by this disease. This pasture can induce hypomagnesemia in pregnant and lactating cattle and sheep. The risk is with young, rapidly growing pasture, either in the spring or in the autumn and winter with pastures planted in late summer. The pasture is usually dangerous for only a few weeks, but heavy losses may occur in all classes of sheep and cattle. Bos taurus breeds are more susceptible to the development of hypomagnesemia than Bos indicus.

Occurrence and Risk Factors for Winter Hypomagnesemia
Hypomagnesemic tetany in cattle wintered in the open causes some losses in the United Kingdom, New Zealand, southern Australia, and the east-central states and Pacific slope of the United States. It occurs in cattle grazed on pasture in the winter with minimal supplemental hay and in cattle grazed on aftermath crops and corn stover. The disease occurs in regions with temperate climates, and risk is increased by exposure to bad weather, which is exacerbated by absence of trees or other shelter in fields and by failure to supply supplementary feed during these cold spells. The disease does not seem to occur in cattle kept outside in prolonged winters where environmental temperature is consistently very low and there is adequate feed. Hypomagnesemia, commonly presenting as chronic hypomagnesemia and sudden death, has been recognized as occurring in housed cattle in the winter in Europe for many years and recently has also been reported in the United States.

Morbidity and Mortality
In all of these forms of the disease, the morbidity rate is highly variable, reaching as high as 12% in individual herds and up to 2% in particular areas. The incidence varies from year to year depending largely on climatic conditions and management practices, and the disease is often limited in its occurrence to particular farms and even to individual fields.

Although an effective treatment is available, the case-fatality rate is high because of the short course. Because animals die before they are observed to be ill, there are not accurate figures on case fatality, but it is probably of the order of 30% in dairy cattle and considerably higher in beef cattle.

There have been few epidemiologic studies specifically addressing the importance of the syndrome. In Finland, a faecal- incidental incidence varying between 0.1% and 0.3% has been recorded, with an increase in parity to at least six for lactation tetany occurring on pasture but not for indoor tetany. No association with other diseases was found other than for milk fever. In Northern Ireland, approximately 10% of dairy cows and 30% of beef cows have subnormal or deficient blood magnesium concentrations during the grazing season, and hypomagnesemia is considered the cause of 20% of the sudden-death mortality in beef cattle. Surveys of beef cattle owners of the relative importance of different diseases invariably rate hypomagnesemia high in importance.

Pasture Risk Factors
In most areas of the world, there is a strong association between risk for hypomagnesemia and systems of pasture improvement and pasture fertilization to increase forage yield. There are a number of influences on the concentration of magnesium and other elements in pasture.

Pasture Species
Hypomagnesemia is a problem on grass-dominant pastures. Concentrations of calcium and magnesium are higher in legumes and forbs than in grasses. Within the grasses, different genotypes of the same species can differ markedly in calcium and magnesium concentrations, and most cool-season grasses have the potential to produce hypomagnesemia. However, there are some differences, and grasses with a high ratio of potassium to calcium and magnesium (e.g., Dactylis glomerata, Lolium perenne, Phalaris arundinacea) are more likely to cause grass tetany than those with low ratios (e.g., Bromus inermis, Poa pratensis, Agrostis spp.). On soil types where the disease is common, cool-season grass pastures top dressed with nitrogenous fertilizers are dangerous, and their toxicity may be increased by the application of potash. Warm-season grasses do not have the same risk, and grass tetany is not a problem in cattle grazing tropical grasses.

Cereal Pastures
The greater tendency of cereal grazing to cause hypomagnesemia is related to a high content of potassium and a low content of magnesium. The tetany hazard, in order of decreasing hazard, is wheat, oats, barley, rye.

Season
High concentrations of potassium and nitrogen and low concentrations of sodium and soluble carbohydrates occur in pastures during the early growing season and during rapid growth following cold, wet periods. Pasture magnesium concentrations may not be depressed, but the K/(Ca + Mg) ratio is increased.

Fertilization
Application of potash and nitrogenous fertilizers to pastures will decrease the concentration of calcium and magnesium in plants and will also increase the concentration of potassium and nitrogen. There is some evidence that nitrate sources of nitrogen depress magnesium less than ammonium sources of nitrogen.

Soil Type
The availability of magnesium to the plant is influenced by soil type, and some deficiencies in plant magnesium can be corrected by soil fertilization with magnesium. There is no strong association with any one soil type, but high potassium concentrations are consistently associated with increased risk for tetany.

Highly leached, acid, sandy soils are particularly magnesium deficient and the most likely to respond to liming and magnesium fertilization. In very acidic soils, high aluminum concentrations may depress magnesium uptake by plants.

A local knowledge of soil type and its influence on magnesium, potassium, calcium, and nitrogen uptake by pastures can allow the judicious selection or avoidance of the use of pastures for at-risk groups during periods of risk for hypomagnesemia.

Animal and Management Risk Factors
Dry Matter Intake
The dry matter and energy intake of ruminants can influence susceptibility to
hypomagnesemia. A reduction in dry matter intake must reduce the magnesium intake; in situations where hypomagnesemia is already present, a further depression of serum magnesium levels can be anticipated when complete or partial starvation occurs. An insufficient intake of fiber in the winter months can precipitate hypomagnesemia in pastured cows and ewes, and lipolysis is accompanied by a fall in serum magnesium.

Period of Food Deprivation

Many outbreaks of hypomagnesemia are preceded by an episode of stress or temporary starvation. Whether chronic hypomagnesemia preexists or not, a period of starvation in lactating cows and ewes is sufficient to produce a marked hypomagnesemia, and the fall may be sufficiently great to cause clinical tetany. A period of bad weather, yarding, transport, or movement to new pastures or the introduction to unpalatable pastures may provide such a period of partial starvation.

Alimentary Sojourn

Diarrhea is commonly associated with lactation tetany on spring pasture and, by decreasing the alimentary sojourn, may also reduce magnesium absorption.

Climate

A close association between climatic conditions and serum magnesium levels has also been observed. Reduced levels occur in adult cattle and sheep exposed to cold, wet, windy weather with little sunshine and no access to shelter or supplementary feed. Supplementary feeding appears to reduce the effect of inclement weather on serum magnesium levels, and it is possible that failure to eat, or depression of appetite, and a negative energy balance during bad weather may be a basic contributing cause to hypomagnesemia in these circumstances.

Animal Movement

Epinephrine release will result in a precipitous fall in serum magnesium, and this may explain the common observation that clinical cases are often precipitated by excitement or movement of the herd.

Intensive Dairies

Intensive dairies that apply effluent on a limited land base can build soil potassium to high concentrations. Silage from these grounds can have a high risk for inducing hypomagnesemia.

Hypomagnesemia in Sheep

Hypomagnesemia occurs in sheep, particularly in Australia and the United Kingdom. The disease is not common, but it appears to be increasingly associated with pasture improvement practices, and it can cause heavy losses in individual flocks. It is more common in ewes bred for milk and lamb production. In outbreaks, ewes with twins are more liable to develop clinical disease than those with singles, and the main occurrence is in ewes 1 to 4 weeks after lambing, with cases up to 8 weeks after lambing.

Disease is often precipitated by a management procedure involving movement and temporary food deprivation, and cases will occur within the first 24 hours following this and for a few days afterward. As in cattle, disease occurs when ewes are placed on lush grass pastures, but it is especially common where ewes in early lactation are placed on young cereal pastures. Losses usually cease when the flock is moved onto rough, unimproved pasture.

Cases also occur in sheep that are exposed to inclement weather when on low nutritive intake. Simultaneous hypomagnesemia and ketosis can occur in ewes after lambing if they are exposed to low feed availability. These cases do not respond well to treatment. Hypomagnesemia in ewes is predisposed by prior pregnancy toxemia in the flock.

PATHOGENESIS

Most evidence points to hypomagnesemia as the cause of the tetanic signs observed, but the concurrent hypocalcemia may have a contributory effect and in many instances may even be the dominant factor. Most clinical cases of the disease have serum magnesium concentrations below 1 mg/dL (0.4 mmol/L) compared with the reference range in cattle of 1.7 to 3.0 mg/dL (0.7 to 1.2 mmol/L), and there is a striking relationship between the incidence of the clinical disease and the occurrence of a seasonal hypomagnesemia.

The reduction in serum concentrations of magnesium is concurrent with a marked fall in the excretion of magnesium in the urine. In affected herds and flocks, many clinically normal cows and sheep have low serum magnesium concentrations. In some of these circumstances a concurrent hypocalcemia may be the precipitating cause.

Magnesium has many influences on impulse transmission in the neuromuscular system, including effects on the release of acetylcholine, on the sensitivity of the motor end plate, on the threshold of the muscle membrane, and on activation of the cholinesterase system. These offer an attractive hypothesis for the muscular irritability seen with the disease. However, it has also been established that magnesium concentrations in the cerebrospinal fluid (CSF) are more predictive of clinical disease than those in serum, which would indicate that alterations in central nervous system (CNS) function are more important than alterations in peripheral nerve function. It is also evident that CSF concentrations of magnesium in hypomagnesemic animals rise significantly after treatment with a magnesium salt. The need for this to happen would explain the delay of about 30 minutes after an IV injection before recovery occurs, because CSF volume turns over at approximately 1% per minute.

CLINICAL FINDINGS

For convenience, lactation tetany is described in acute, subacute, and chronic forms.

Acute Lactation Tetany

In acute lactation tetany, the animal may be grazing at the time and suddenly cease to graze, adopt a posture of unusual alertness, and appear uncomfortable; twitching of the muscles and ears is also evident. There is severe hyperesthesia, and slight disturbances precipitate attacks of continuous belowing, frenzied galloping, and occasionally aggression. The gait becomes staggering, and the animal falls, with obvious tetany of the limbs, which is rapidly followed by clinical convulsions lasting for about a minute. During the convulsive episodes the following characteristics are common:

- Opisthotonos
- Nystagmus
- Champing of the jaws
- Frothing at the mouth
- Pricking of the ears
- Retraction of the eyelids

Between episodes, the animal lies quietly, but a sudden noise or touch may precipitate another attack.

The temperature rises to 40.0 to 40.5°C (104 to 105°F) after severe muscle exertion; the pulse and respiratory rates are also high. The absolute intensity of the heart sounds is increased so that they can be heard some distance away from the cow. Death usually occurs within 5 to 60 minutes, and the mortality rate is high because many die before treatment can be provided. The response to treatment is generally good if the animal is treated early.

Subacute Lactation Tetany

In subacute lactation tetany, the onset is more gradual. Over a period of 3 to 4 days, there is slight inappetence, wildness of the facial expression, and exaggerated limb movements. The cow often resists being driven and throws her head about as though expecting a blow. Spasmodic urination and frequent defecation are characteristic. The appetite and milk yield are diminished, and ruminal movements decrease. Muscle tremor and mild tetany of the hindlegs and tail with an unsteady, straddling gait may be accompanied by retraction of the head and trismus. Sudden movement or noise, the application of restraint, or the insertion of a needle may precipitate a violent convolution.

Animals with this form of the disease may recover spontaneously within a few days or progress to a stage of recurrency with a similar but rather milder syndrome than in the acute form. Treatment is usually effective, but there is a marked tendency to relapse.
Chronic Hypomagnesemia
Many animals in affected herds have low serum magnesium levels but do not show clinical signs. There may be sudden death. A few animals exhibit a rather vague syndrome that includes dullness, unthriftiness, and indifferent appetite and may subsequently develop one of the more obvious syndromes. In lactating cows, this may be the development of paralys and a milk-fever-like syndrome that is poorly responsive to calcium treatment. Depressed milk production has also been attributed to chronic hypomagnesemia in dairy herds in New Zealand. The chronic type may also occur in animals that recover from the subacute form of the disease.

Parturient Paresis With Hypomagnesemia
This syndrome is described in the discussion of parturient paresis and consists of paresis and circulatory collapse in an adult cow that has calved within the preceding 48 hours but in which dullness and flaccidity are replaced by hyperesthesia and tetany.

CLINICAL PATHOLOGY
Serum or urinary magnesium concentrations can be used for clinical cases. Where an animal is dead and hypomagnesemia is suspect, a presumptive diagnosis can be made from samples taken from other at-risk animals in the group or from the vitreous humor of the dead animal. An acute-phase inflammatory response with leukocytosis and increased numbers of neutrophils and monocytes has been recorded in ruminants and laboratory animals fed magnesium-deficient diets.

Serum Magnesium Concentrations
Normal serum magnesium concentrations are 1.7 to 3.0 mg/dL (0.70 to 1.23 mmol/L). These levels in cattle are often reduced in seasonal subclinical hypomagnesemia to between 1 and 2 mg/dL (0.41 and 0.82 mmol/L), but risk for tetany is not present until the level falls to below 1.2 mg/dL (0.49 mmol/L).

The average concentration at which signs occur is approximately 0.5 mg/dL (0.21 mmol/L), and in sheep it is suggested that clinical tetany does not occur until the serum magnesium concentration is below 0.5 mg/dL (0.21 mmol/L).

Serum magnesium concentration in some animals may fall to as low as 0.4 mg/dL (0.16 mmol/L) without clinical illness. This may be a result of individual animal variation in the degree of ionization of the serum magnesium and in the difference between serum and CSF concentrations. A transitory elevation of serum magnesium concentration occurs after violent muscular exercise in cattle with clinical signs of hypomagnesemia.

Total serum calcium concentrations are often reduced to 5 to 8 mg/dL (1.25 to 2.00 mmol/L), and this may have an important bearing on the development of clinical signs. Serum inorganic phosphate concentrations may or may not be low.

In wheat pasture poisoning of cattle there is hypomagnesemia, hypocalcemia, and hyperkalemia. In acute tetany, serum potassium concentrations are usually dangerously high and may contribute to the high death rate.

Magnesium Concentrations in Cerebrospinal Fluid
Magnesium concentrations in CSF can be used as a diagnostic procedure, but CSF is not easily or safely collected in tetany cases. CSF collected up to 12 hours after death can be used diagnostically.

Magnesium concentrations in CSF of 1.25 mg/dL (0.51 mmol/L) were found in tetanic cows with hypomagnesemia (serum magnesium concentrations of 0.54±0.41 mg/dL; 0.22±0.17 mmol/L). In clinically normal cows with hypomagnesemia, comparable concentrations in CSF were 1.84 mg/dL (0.74 mmol/L) and 0.4 mg/dL (0.16 mmol/L) in serum. In normal animals CSF concentrations are the same as in plasma, that is, 2.0 mg/dL (0.82 mmol/L) and up. The magnesium content of ventricular CSF may be quite different from that of lumbar CSF. Ventricular CSF is also more responsive to changes in serum magnesium concentrations and is preferred for diagnosis at necropsy.

Vitreous Humor
Magnesium concentrations in vitreous humor (but not aqueous humor) can be measured because vitreous hume magnesium concentration remains stable for a longer period of time than magnesium concentrations in serum or CSF. In general, vitreous hume magnesium concentrations less than 0.55 mmol/L for cattle and less than 0.65 mmol/L for sheep up to 48 hours after death indicate the presence of hypomagnesemia, particularly at ambient temperatures of 4°C or 20°C.

Vitreous humor is viscous and must be collected using a 14-gauge (preferably) or 16-gauge needle attached to a syringe. With the deceased animal placed in sternal recumbency, the needle is introduced vertically from a position caudal to the dorsal limbus of the eye parallel and caudal to the lens before aspiration (Fig. 17-5). The needle position should be altered to facilitate aspiration. The aspirated sample should be placed in a plain tube and centrifuged, and the supernatant should be submitted for determination of the magnesium concentration. Aqueous humor should not be collected for analysis because it is readily contaminated by degenerating iris tissue and evaporation of free water across the cornea.

Urine Magnesium Concentrations
The occurrence of low urine magnesium levels is good presumptive evidence of hypomagnesemia; however, it is not the most sensitive test. Normalization of urine magnesium to simultaneously determine urine creatinine concentration will adjust urine magnesium concentration for animal-to-animal variability in urine concentration. Further adjustment by calculating the fraction clearance of magnesium (requiring simultaneous determination of plasma/serum magnesium and creatinine concentrations) has not been shown to provide additional information beyond that provided by the concentration of urinary magnesium to creatinine alone.

Herd Diagnosis
The kidney is the major organ of homeostasis, and it has been argued that analysis of urine magnesium status is a more accurate method of assessing herd magnesium status than serum magnesium concentrations. The magnesium status of a herd, and the need to supplement the diet to prevent lactation tetany, can be established from the following values:

- serum magnesium concentrations
- urine magnesium concentrations
- urinary magnesium fractional clearance
- creatinine-corrected urinary magnesium concentrations

Laboratory charges for urinary magnesium fractional clearance ratios are expensive. The determination of the creatinine-corrected urinary magnesium concentration from 10 cows in a herd has been found to be a more sensitive indicator of magnesium status of the herd than estimates from serum, and it is a better predictor of response to supplementation. Values of less than 1.0 mmol/L indicate that a positive response to supplementation is likely. Urine
magnesium concentrations below 1.0 mg/dL (0.4 mmol/L) indicate a danger for tetany.

**NECROPSY FINDINGS**

There are no specific necropsy findings. Extravasations of blood may be observed in subcutaneous tissues and under the pericardium, endocardium, pleura, peritoneum, and intestinal mucosa. Agonal emphysema may also be present.

The magnesium content of the bovine vitreous humor is considered to be an accurate estimate of magnesium status for 72 hours after death, provided the environmental temperature does not exceed 23°C (73°F) and there is not growth of bacterial contamination after sampling, which can result in a false low magnesium concentration. The addition of a small amount of 4% formaldehyde (3% of the vitreous humor volume) will allow accurate analysis for periods up to 72 hours after sampling.

Concentrations in the aqueous humor are not stable after death.

**DIFFERENTIAL DIAGNOSIS**

**Cattle**
- Acute lead poisoning
- Rabies
- Nervous ketosis
- Bovine spongiform encephalopathy

**Sheep**
- Hypocalcemia
- Phalaris poisoning
- “Stagger” syndromes

**TREATMENT**

IV administration of preparations containing magnesium or, more commonly, magnesium and calcium are used. The efficiency of the various treatments appears to vary from area to area, and even within areas under different conditions of management and climate. Response rates and recovery rates are much higher in cases treated early in the clinical course. IV chloral hydrate may be administered to reduce the severity of convulsions during treatment with magnesium. Case fatality, even with therapy, can be high, especially in advanced cases.

**Combined Calcium/Magnesium Therapy**

The safest general recommendation is to use a combined calcium–magnesium preparation (e.g., 500 mL of a solution containing 25% calcium borogluconate and 5% magnesium hypophosphite for cattle, 50 mL for sheep and goats) IV followed by an SC injection of a concentrated solution of a magnesium salt. The details and risks of administration of the type of solution are described in the section on parturient paresis. A combination of 12% magnesium adipate and 5% calcium gluconate at a dose rate of 500 mL is also used.

**Magnesium Therapy**

When magnesium solutions are used, 200 to 300mL of a 20% solution of magnesium sulfate may be injected IV; this is followed by a very rapid rise in serum magnesium concentration, which returns to preinjection levels within 3 to 6 hours. A much slower rise and fall occurs after SC injection, and for optimum results the SC injection of 200 mL of a 50% solution of magnesium sulfate has been recommended. A rise in serum magnesium of 0.5 mg/dL (0.21 mmol/L) occurs within a few minutes, and subsequent serum concentrations do not go above 5 mg/dL (2.06 mmol/L). In cases where serum magnesium concentrations are low because of seasonal hypomagnesemia, the injection of magnesium salts is followed by a rise and then a return to the subnormal preinjection levels.

The IV injection of magnesium salts is not without danger. It may induce cardiac dysrhythmia, or medullary depression may be severe enough to cause respiratory failure. If signs of respiratory distress or excessive slowing or increase in heart rate are noticed, the injection should be stopped immediately and, if necessary, a calcium solution injected.

The substitution of magnesium lactate for magnesium sulfate has been recommended to provide a more prolonged elevation of serum magnesium levels. A dilute solution (3.3%) causes minimal tissue injury and can be administered IV or SC. Magnesium gluconate has also been used as a 15% solution at doses of 200 to 400 mL. High serum magnesium concentrations are obtained more slowly and are maintained longer with magnesium gluconate than with magnesium sulfate. The feeding of magnesium-rich supplements, as described in the following section on control, is recommended after parenteral treatment.

**Provision for Further Cases**

The predisposing factors that lead to a case of hypomagnesemia apply to the herd as a whole, and it is probable that further clinical cases will occur before the effects of corrective strategies are observed. In extensive range situations, it is advisable to instruct the owner on how to treat cases because a delay in treatment can markedly increase the rate of treatment failures. SC treatment is within the realm of most, but successful therapy is also recorded by the rectal infusion of 30 g of magnesium chloride in a 100-mL solution; serum concentrations of magnesium return to normal levels within 10 minutes of administration.

**CONTROL**

Where possible, animals at high risk should be moved to low-risk pastures during the grass tetany season. High-risk pastures can be grazed by low-risk animals, steers, or yearling heifers, for example, during this period.

The occurrence of hypomagnesemia can be corrected by the provision of adequate or increased amounts of magnesium in the diet. A requirement as high as 3.0 g/kg DM diet may be required for lactating cows on spring pasture. The problem is in determining an adequate delivery system, and this will vary according to the management system. Thus blocked minerals containing magnesium or foliar dressing of magnesium may be adequate delivery systems where there is a high stocking density of cattle, but they are totally inadequate or economically unfeasible on range with one cow per 20 acres.

Magnesium oxide is commonly used for supplementation, but other magnesium salts can be used, and they have an approximate equivalent availability. The biological availability of magnesium from magnesium carbonate, magnesium oxide, and magnesium sulfate for sheep is influenced by particle size, but it has been determined as 43.8%, 50.9%, and 57.6%, respectively.

**Feeding of Magnesium Supplements**

The preventive measure that is now universally adopted is the feeding of magnesium supplements to cows during the danger period. The feeding of magneite (containing not less than 87% magnesium oxide), or other sources of magnesium oxide, prevents the seasonal fall in serum magnesium concentrations. Daily administration by drenching, or in the feed, of at least 60 g of magnesium oxide per day is recommended to prevent the disease. This is not always completely effective, and in some circumstances large doses may be necessary. Daily feeding of 120 g is safe and effective, but 180 g daily may cause diarrhea. The dose for sheep and goats is 7 g daily or 14 g every second day. Magnesium phosphate (53 g/d) is also a safe and effective way of ensuring a good intake of magnesium. The protection afforded develops within several days of commencing administration and terminates abruptly after administration ceases.

**Problems With Palatability**

The problem with magnesium supplements is getting the stock to eat the required amount because they are unpalatable. This can be partially countered by mixing the supplement with molasses in equal parts and allowing free access to the mixture or feeding it in ball feeders, but uniform intake by all animals does not occur, and at-risk animals may still develop hypomagnesemic tetany. Similarly, magnesium blocks may have limited efficacy in preventing hypomagnesemia. **Salt blocks** can help repair the sodium deficiency associated with young spring grasses and improve the Na:K ratio in the rumen. If they also contain Mg they can be
an aid in prevention, but usually, by themselves, they do not guarantee freedom from risk for tetany.

Spraying on Hay
One method of attempting to ensure an adequate intake of magnesium is to spray it on hay and to feed this hay as a supplement during periods of grass tetany risk. The common practice is as follows:
1. Mix magnesite with molasses.
2. Dilute mixture with water.
3. Spray mixture onto hay in the windrows when it is being made.
4. Inject mixture into the bales before feeding or spray onto the hay at feeding.
5. Tip bale of hay so that the cut side is uppermost and pour the mixture evenly over the entire surface area.
6. Determine the level of application by the amount of hay intended to be fed.

Depending on local circumstances, this method may or may not be effective because cattle and sheep will frequently not eat hay when on spring pasture unless they are confined for that purpose.

Pellets
Magnesium-rich pellets suggest themselves as a means of supplementation when the additional cost can be borne. Palatability is again a problem, and care needs to be taken to include palatable material in the pellets; alternatively, they may be mixed with other grain or molasses for feeding. Calves should be restricted from access because magnesium oxide at high levels of intake (2% and 4% of the ration) is toxic to calves and causes diarrhea with much mucus in the feces.

In some high-risk situations it may be advisable to provide magnesium in several forms to ensure adequate intake.

Routine Daily Drenching
A once-daily oral administration of magnesium oxide or magnesium chloride to lactating dairy cows (to provide 10 g magnesium per cow), administered with a drenching gun just before the cows leave the milking parlor, is used in New Zealand to ensure adequate supplemental magnesium during periods of high risk. The cows become used to the procedure (and the farmers adept at carrying it out), and it causes minimal disruption of management.

Heavy Magnesium “Bullets”
The use of heavy “bullets” of magnesium to prevent hypomagnesemia has been effective in laboratory trials, and they are available commercially in some countries. The objective is to place a heavy bullet of magnesium in the reticulum, from which it constantly liberates small amounts of magnesium—about 1 g/d. This objective is achieved, and the occurrence of the clinical disease is usually greatly reduced but not eliminated. In dangerous situations, it is customary to administer up to four bullets at a time. As with all bullets, there is a proportion lost by regurgitation and by passage through the gut. A special sheep-sized bullet is used in ewes, with similar results.

Top Dressing of Pasture
Top dressing of pasture, together with magnesium-rich fertilizers, raises the level of magnesium in the pasture and decreases the susceptibility of cattle to hypomagnesemia. For top dressing, calcined magnesite (1125 kg/ha) or magnesium limestone (5600 kg/ha) are satisfactory, with the former resulting in a greater increase in pasture magnesium.

Other magnesium-containing fertilizers can be used depending on cost. The duration of the improved magnesium status varies with the type of soil: it is greatest on light sandy loams, on which a dressing of 560 kg/ha of calcined magnesium can provide protection for 3 years. On heavy soils protection for only 1 year is to be expected. To avoid unnecessary expense, it may be possible to top dress one field with the magnesium fertilizer and keep this field in reserve for spring grazing. Fertilization with magnesium is expensive, and the response of pastures varies markedly with the soil type. It is advisable to seek agronomic advice.

Foliar Dusting and Spraying
The magnesium content of pastures can be raised much more quickly by spraying with a 2% solution of magnesium sulfate at fortnightly intervals or by application of very finely ground magnesium oxide to the pasture (30 kg/ha) before grazing commences. The technique is referred to as foliar dusting or spraying and has the advantage over feed supplementation that the intake is standard. It is very effective in cattle in maintaining serum magnesium concentrations and preventing the occurrence of the clinical disease. Dusting with 20 to 50 kg MgO/ha can provide protection for up to 3 weeks, but the duration is adversely influenced by wind and rain. A MgO-bentonite-water slurry sprayed onto pastures (26 kg MgO and 2.6 kg bentonite/ha) is effective in providing protection in high-rainfall periods.

Provision in Drinking Water
The problem with water medication is that the water intake of the group to be treated is not known and may be minimal on rapidly growing pastures. However, water medication may provide a delivery system for magnesium on management systems such as extensive range pastures where other methods may have limited success. Water sources other than the medicated supply need to be fenced off or otherwise restricted. The addition of magnesium sulfate (500 g/100 L) or magnesium chloride hexahydrate (420 g/100 L) to the water supply during the risk period for hypomagnesemia has proved effective.

Management of Pasture Fields
The economics of dairy farming make it necessary to produce maximum pasture growth, and the development of tetany-prone pastures is unavoidable in many circumstances. In some areas it may be possible to reduce the danger of such pastures by encouraging the development of legumes. In other areas the period of legume growth does not coincide with the period of maximum risk for grass tetany.

Restricting the amount of potash added to pastures, especially in the period immediately preceding the risk period for tetany, or using potash fertilizers in the autumn or late spring after the period of risk can reduce the risk of the disease. The grazing of low-risk animals on high-risk pastures is another strategy. Ensuring that ample salt is available during the danger period to counteract the high intake of potassium can also reduce the risk of the disease.

Plant geneticists are developing cultivars of cool-season grasses with high magnesium content that could be used for grazing during the tetany season. Lactating sheep grazing a high-magnesium cultivar of perennial rye grass (Lolium perenne cv Radmore) in the spring have shown higher serum magnesium concentrations than sheep grazing control cultivar, and cultivars of tall fescue (Festuca arundinacea) with high magnesium and calcium concentrations and low tetany potential are also available.

Provision of Shelter
In areas where winter pasturing is practiced, the observation that serum magnesium levels fall during the winter and in association with inclement weather suggests that cattle and sheep should be provided with shelter at such times. If complete housing is impractical, it may be advisable to erect open-access shelters in those fields that have no tree cover or protection from prevailing winds. Fields in which lactating cows are kept should receive special attention in this regard. Unfortunately, the disease is most common on highly improved farms, where most natural shelter has been removed, and it is desired to keep the cows on the highly improved pasture to maintain milk production or fatten calves rapidly.

Time of Calving
In areas where the incidence of the disease is high, it may be advisable to avoid having the cows calve during the cold winter months when seasonal hypomagnesemia is most likely to develop. Unfortunately, it is often important to have cows calve in late winter to take advantage of the flush of spring growth when the cows are at the peak of their lactation.
Feeding on Hay and Unimproved Pasture

Because of the probable importance of lush, improved, grass pasture in producing the disease, the provision of some grain, hay, or rough grazing may reduce its incidence. It is most important that the periods of fasting, such as occur when cattle or sheep are yarded or moved or during bad weather, should be avoided, especially in lactating animals and when seasonal hypomagnesemia is likely to be present.

**REFERENCES**

**FURTHER READING**

**ETIOLOGY**

The disease results when the dietary intake of magnesium is inadequate for the requirements of the calf. Affected animals may have concurrent hypocalcemia.

**Magnesium Homeostasis in the Calf**

Milk has low concentrations of magnesium. A milk diet provides adequate magnesium for the requirements of a growing calf up to a body weight of approximately 50 kg, but if milk is the sole diet, the intake of magnesium will be inadequate for requirements once this body weight is reached. The deficit will persist if the other feeds that are fed are also inadequate in magnesium.

In the young calf, magnesium is absorbed in the intestine; however, the efficiency of magnesium absorption decreases from 87% to approximately 30% at 3 months of age, when maximum susceptibility to the disease occurs. The efficiency of absorption is also decreased by a reduction in intestinal transit time caused by diarrhea.

In contrast to adult cattle, young calves can mobilize body stores of magnesium, which are principally located in the skeleton. Approximately 40% of the magnesium stored in the skeleton can be mobilized, which will protect against a short-term deficit.

Hypomagnesemic tetany in calves is often complicated in field cases by the coexistence of other diseases, especially enzootic muscular dystrophy.

**EPIDEMIOLOGY**

**Occurrence**

The disease is not common. Cases may occur sporadically, or a number of deaths may occur on one farm within a short period of time.

**Risk Factors**

The disease can occur under a number of different circumstances. Most commonly, hypomagnesemic tetany occurs in calves 2 to 4 months of age or older that are fed solely on a diet of whole milk, and calves receiving the greatest quantity of milk and growing most rapidly are more likely to be affected because of their greater need for magnesium for incorporation into developing soft tissues. It is most likely to occur in calves being fattened for veal. Those cases that occur in calves on milk replacer appear to be related to chronic scours and the low magnesium content of the replacer. This problem is less common than it once was because most modern commercial milk replacers have added adequate magnesium.

A significant loss of magnesium in the feces also occurs in calves allowed to chew fibrous material, such as bedding; the chewing stimulates profuse salivation and creates greater loss of endogenous magnesium. Peat and wood shavings are bedding materials known to have this effect.

Cases have also been reported in calves fed milk-replacer diets or milk, concentrates, and hay, and in calves running at pasture with their dams. Deaths resulting from hypomagnesemic tetany have also occurred in 3- to 4-month-old calves whose hay and silage rations were low in magnesium content.

Hypomagnesemia also occurs in young cattle, about 6 months of age, that are being fattened intensively indoors for the baby beef market. The phosphorus content of their diet is high, and a lack of vitamin D is probable. The situation is exacerbated by a shortage of roughage. The hypomagnesemia is accompanied by hypocalcemia.

**Experimental Reproduction**

A condition closely resembling the field syndrome has been produced experimentally by feeding an artificial diet with a very low content of magnesium and a high calcium content, and biochemical hypomagnesemia is readily produced in calves with a diet based on skim milk and barley straw. Hypomagnesemia has also been produced experimentally in very young foals by feeding a diet with a very low magnesium content. The clinical signs are similar to those in calves, and the calcification found in the walls of vesicles of calves also occurs in foals.

**PATHOGENESIS**

On affected farms, calves are born with normal serum magnesium concentrations of 2 to 2.5 mg/dL (0.82 to 1.03 mmol/L), but the concentrations fall gradually in the succeeding 2 to 3 months, often to below 0.8 mg/dL (0.33 mmol/L). Tetany does not occur until the serum magnesium falls below this concentration and is most severe at concentrations below 0.6 mg/dL (0.25 mmol/L), although some calves in a group may have...
concentrations even lower than this and show few clinical signs.

Magnesium deficiency inhibits the release and action of parathyroid hormone, and this is thought to be the genesis of the concurrent hypocalcemia. It is probable that depression of the serum calcium level precipitates tetany in animals rendered tetany prone by low serum magnesium levels. Tetanic convulsions can occur in hypocalcemic calves in the absence of hypomagnesemia.

Hypomagnesemic tetany is not related in any way to enzootic muscular dystrophy, although the diseases may occur concurrently.

CLINICAL FINDINGS

The first sign in the experimental disease is constant movement of the ears. The temperature is normal and the pulse rate accelerated. Hyperesthesia to touch and grossly exaggerated tendon reflexes with clonus are present. Shaking of the head, opisthotonos, ataxia without circling, and a droopy, backward carriage of the ears are constant. There is difficulty in drinking because of the animal's inability to get to the bucket.

Initially, the calves are apprehensive, show agitation and retraction of the eyelids when approached, and are hypersensitive to all external stimuli, but they show no tetany. Later, fine muscle tremors appear, followed by kicking at the belly, frothing at the mouth, and spasticity of the limbs. Convulsions follow, beginning with stamping of the feet, head retraction, chomping of the jaws, and falling.

During the convulsions the following signs are present:

- Jaws are clenched.
- Respiratory movements cease.
- There are tonic and clonic movements of the limbs.
- There is involuntary passage of urine and feces.
- There are cycles of protrusion and retraction of the eyeballs.

The pulse rate rises to 200 to 250/min, and the convulsions disappear momentarily. The pulse becomes impalpable, and cyanosis appears before death.

In field cases the signs are almost identical, but they are rarely observed until the terminal tetanic stage. Older calves usually die within 20 to 30 minutes of the onset of convulsions, but young calves may recover temporarily only to succumb to subsequent attacks. Cases that occur in young calves with scours, usually at about 2 to 4 weeks of age, show ataxia, hyperesthesia, opisthotonos, and convulsions as the presenting signs. The convulsions are usually continuous, and the calves die within 1 hour.

CLINICAL PATHOLOGY

Serum magnesium concentrations below 0.8 mg/dL (0.33 mmol/L) indicate severe hypomagnesemia, and clinical signs occur with levels of 0.3 to 0.7 mg/dL (0.12 to 0.29 mmol/L). Normal values are 2.2 to 2.7 mg/dL (0.9 to 1.11 mmol/L). Erythrocyte magnesium concentrations are also low, indicating a chronic deficiency. Serum calcium concentrations tend to fall when serum magnesium levels become very low and are below normal in most clinical cases.

The estimation of the magnesium in bone (particularly ribs and vertebrae) is a reliable confirmatory test at necropsy. Values below a ratio of 70:1 for calcium : magnesium may be regarded as normal, and those above 90:1 are indicative of severe magnesium depletion. In the normal calf the ratio is about 55:1. Absolute bone calcium values are not decreased and are often slightly elevated. An incidental change is the marked increase in serum creatinine kinase activity in calves after an acute attack of hypomagnesemic tetany.

NECROPSY FINDINGS

There is a marked difference between the necropsy lesions of some natural cases and those in the experimental disease. In field cases, there is often calcification of the spleen and diaphragm, and calcified plaques are present in the aorta and endocardium, together with hyaline degeneration and musculature. In other cases necropsy lesions similar to those in enzootic muscular dystrophy occur.

In experimentally produced cases these lesions are not evident, but there is extensive congestion in all organs, and hemorrhages are present in unsupported organs, including the following:

- Gallbladder
- Ventricular epicardium
- Pericardial fat
- Aorta
- Mesentery wall
- Intestinal wall

The lesions are obviously terminal and are associated with a terminal venous necrosis. Some field cases present a picture identical to this.

Differential Diagnosis

- Acute lead poisoning
- Enterotoxemia caused by Clostridium perfringens type D
- Polioencephalomalacia
- Tetanus
- Vitamin A deficiency
- Meningitis

Follow-up supplementation of the diet with magnesium oxide or carbonate as described later is advisable. Chloral narcosis or tranquillization with an ataractic drug may be essential to avoid death as a result of respiratory paralysis during convulsions.

CONTROL

The provision of hay that is high in magnesium, such as alfalfa, helps to prevent the disease, as will well-formulated concentrates.

Supplementary Feeding of Magnesium

If begun during the first 10 days of life, supplementary magnesium feeding will prevent excessive drops in serum magnesium, but if begun after the calf is 7 weeks old, it may not prevent further depression of the levels. Supplementation should continue until at least 10 weeks of age. Daily feeding of the magnesium compound and fairly accurate dosing are necessary to avoid scouring or inefficient protection. For calves of average growth rate, appropriate dose rates are 1 g/d for calves to 5 weeks of age, 2 g/d for calves 5 to 10 weeks of age, and 3 g/d for calves 10 to 15 weeks of age of magnesium oxide or twice this dose of carbonate. Supplementation of the diet with magnesium restores serum calcium levels to normal and corrects the hypomagnesemia.

Magnesium Alloy Bullets

Two bullets of the sheep size (together releasing approximately 1 g/d of magnesium) per calf have shown high efficiency in preventing the clinical disease and also the hypomagnesemia that precedes it. Calves kept indoors and fed largely on milk should get adequate mineral supplement and vitamin D (70,000 IU vitamin D₃/d). Magnesium utilization will not be affected, but calcium absorption, which is often sufficiently reduced to cause a concurrent hypocalcemia, will be improved.

TRANSPORT RECUMBENCY OF RUMINANTS

Transport recumbency (tetany) occurs after prolonged transport, usually in cows and ewes in late pregnancy. It is also recorded in lambs transported to feedlots and in cows and sheep delivered to abattoirs. It is characterized by recumbency, alimentary tract stasis, and coma, and it is highly fatal. It occurs in most countries. Large losses can be encountered when cows and ewes in late pregnancy are moved long distances by rail, by truck, or on foot.

Although cows of any age in late pregnancy are most commonly affected, the disease has also been recorded in cows...
recently calved, bullocks, steers, dry cows, and lambs. Risk factors include the following:

- Heavy feeding before shipment
- Deprivation of feed and water for more than 24 hours during transit
- Unrestricted access to water
- Exercise immediately after unloading

There is an increased incidence of the disease during hot weather. The cause is unknown, although physical stress is an obvious factor. Lambs show the following characteristics:

- Restlessness
- Staggering
- Partial paralysis of hindlegs
- Early assumption of lateral recumbency

Death may occur quickly, or after 2 to 3 days of recumbency. There is mild hypocalcemia (7 to 7.5 mg/dL; 1.75 to 1.87 mmol/L). The recovery rate even with treatment is only fair. Clinical signs may occur while the cattle are still in the transportation vehicle or up to 48 hours after unloading. In the early stages, animals may exhibit excitement and restlessness, trismus, and grinding of the teeth. A staggering gait with padding of the hindlegs and recumbency occur, accompanied by stasis of the alimentary tract and complete anorexia. Animals that do not recover gradually become comatose and die in 3 to 4 days. There may be moderate hypocalcemia and hypophosphatemia in cattle. In sheep of various ages, some are hypocalemic and hypomagnesemic, some are hypoglycemic, and some have no detectable biochemical abnormality. There are no lesions at necropsy other than those related to prolonged recumbency. Ischemic muscle necrosis is the most obvious of these lesions. The relationship of the disease to transport or forced exercise is diagnostic.

Some cases respond to treatment with combined calcium, magnesium, and glucose injections. Repeated parenteral injections of large volumes of electrolyte solutions are recommended. In lambs, the SC injection of a solution of calcium and magnesium salts is recommended, but the response is usually only 50%, due probably because of an intercurrent myonecrosis.

If prolonged transport of cows or ewes in advanced pregnancy is unavoidable, they should be provided with adequate food, water, and rest periods during the trip. The incidence of this condition after transportation appears to have been markedly reduced with increased monitoring and awareness of transportation-related morbidity and mortality.

**KETOSIS AND SUBCLINICAL KETOSIS (HYPERKETONEMIA) IN CATTLE**

**SYNOPSIS**

**Etiology** A multifactorial disorder of energy metabolism. Negative energy balance

- Results in hypoglycemia, ketonemia (the accumulation in blood of acetoacetate, \(\beta\)-hydroxybutyrate (BHB) and their decarboxylation products acetone and isopropanol), and ketonuria.

**Epidemiology** Primary ketosis and subclinical ketosis occurs predominantly in well-conditioned cows with high lactation potential, principally in the first month of lactation, with a higher prevalence in cows with a higher lactation number. Loss of body condition in the dry period and immediately postpartum. Secondary ketosis occurs where other disease reduces feed intake.

**Clinical findings** Cattle show wasting with decrease in appetite, body condition, and milk production. Some have short periods of bizarre neurologic and behavioral abnormality (nervous ketosis). Response to treatment is good. Subclinical ketosis (hyperketonemia) is detected by tests for ketones, usually BHB in blood, plasma, or serum, and acetoacetate in urine.

**Clinical pathology** Hypoglycemia, ketonemia, ketonuria, or elevated ketone in milk.

**Necropsy findings** None specific. Varying degrees of hepatic lipidosis.

**Diagnosis confirmation** Ketonemia, ketonuria, or, less commonly, elevated ketone concentration in milk.

**Treatment** Intravenous glucose, parenteral corticosteroid, and oral glucose precursors such as propylene glycol. The disease responds readily to treatment in cattle with mild hepatic lipoidosis and is self-limiting.

**Control** Correction of energy imbalance. Herd biochemical monitoring coupled with condition scoring. Daily monensin administration to late-gestation and early-lactation dairy cows.

**ETIOLOGY**

**Glucose Metabolism in Cattle**

The maintenance of adequate concentrations of glucose in the plasma is critical to the regulation of energy metabolism. The ruminal absorbs very little dietary carbohydrate as hexose sugar because dietary carbohydrates are fermented in the rumen to short-chain fatty acids, principally acetate (70%), propionate (20%), and butyrate (10%). Consequently, glucose needs in cattle must largely be met by gluconeogenesis. Propionate and amino acids are the major precursors for gluconeogenesis, with glycerol and lactate being of lesser importance.

Propionate is produced in the rumen from starch, fiber, and proteins. It enters the portal circulation and is efficiently removed by the liver, which is the primary glucose-producing organ. Propionate is the most important glucose precursor; an increased availability of propionate can spare the hepatic utilization of other glucose precursors, and production of propionate is favored by a high grain inclusion in the diet. The gluconeogenic effect of propionate should be contrasted to acetate, which is transported to peripheral tissues and to the mammary gland and metabolized to long-chain fatty acids for storage as lipids or secretion as milk fat.

**Amino acids.** The majority of amino acids are glucogenic and are also important precursors for gluconeogenesis. Dietary protein is the most important quantitative source, but the labile pool of body protein (particularly skeletal muscle) is also an important source; together they contribute to energy synthesis, milk lactose synthesis, and milk protein synthesis.

**Energy Balance**

In high-producing dairy cows there is always a negative energy balance in the first few weeks of lactation. The highest dry matter intake does not occur until 8 to 10 weeks after calving, but peak milk production is at 4 to 6 weeks, and energy intake may not keep up with demand. In response to a negative energy balance and low serum concentrations of glucose (and consequently low serum concentrations of insulin), cows will mobilize adipose tissue, with consequent increases in serum concentrations of nonesterified fatty acids (NEFA) and subsequent increases in serum concentrations of \(\beta\)-hydroxybutyrate (BHB), acetocetate, and acetone. The hepatic mitochondrial metabolism of fatty acids promotes both gluconeogenesis and ketogenesis. Cows partition nutrients during pregnancy and lactation and are in a lipolytic stage in early lactation and at risk for ketosis during this period.

**Hepatic Insufficiency in Ketosis**

Hepatic insufficiency has been shown to occur in bovine ketosis, but it does not occur in all cases. Ketosis is defined as an increased plasma or serum concentration of ketoacids and is divided into three types. In type I, or "spontaneous" ketosis, the gluconeogenic pathways are maximally stimulated, and ketosis occurs when the demand for glucose outstrips the capacity of the liver for gluconeogenesis because of an insufficient supply of glucose precursors. Rapid entry of NEFAs into hepatic mitochondria occurs and results in high rates of ketogenesis and high plasma/serum ketone concentration. There is little conversion of NEFAs to triglycerides, resulting in little fat accumulation in the liver. In type II ketosis, manifest with fatty liver, gluconeogenic pathways are not maximally stimulated, and consequently mitochondrial uptake of NEFAs is not as active, and NEFAs become esterified in the cytosol, forming triglyceride. The capacity of cattle to transport triglyceride from the liver is low, resulting in accumulation and fatty liver. The occurrence of a fatty liver can further suppress hepatic gluconeogenic capacity. Hepatic insufficiency may occur more commonly in those cows predisposed to ketosis by overfeeding in the dry period. In type III ketosis, cattle...
are fed a diet (typically a high-maize ration) that results in a higher ruminal production of butyrate, which is directly metabolized by ruminal epithelial cells to butyrate.

**Ketone Formation**

Ketones arise from two major sources: butyrate in the rumen and mobilization of fat. A large proportion of butyrate produced by rumen fermentation of the diet is converted to BHB in the rumen epithelium and is absorbed as such. Free fatty acids produced from the mobilization of fat are transported to the liver and oxidized to produce acetyl-CoA and NADH.

Acetyl-CoA may be oxidized via the tricarboxylic acid (TCA) cycle or metabolized to acetoacetyl-CoA. Complete oxidation of acetyl-CoA via the TCA cycle depends on an adequate supply of oxaloacetate from the precursor propionate. If propionate, and consequently oxaloacetate, is deficient, oxidation of acetyl-CoA via the TCA cycle is limited, and acetyl-CoA is metabolized to acetoacetol CoA and subsequently to acetoacetate and BHB.

The ketones BHB and acetoacetate can be utilized as energy sources. They are normally present in the plasma-serum of cattle, and their concentration is a result of the balance between production in the liver and utilization by the peripheral tissues. Acetoacetate can spontaneously convert to acetone, which is volatile and therefore exhaled in the breath; diffusion of acetone across the rumen epithelium into the rumen means that some acetone is eructated. Ruminal flora (most likely bacteria) can metabolize acetone to isopropanol, which can then be absorbed to increase plasma concentrations of isopropanol, a 3-carbon alcohol.

**Role of Insulin and Glucagon**

The regulation of energy metabolism in ruminants is primarily governed by insulin and glucagon. Insulin acts as a glucoregulatory hormone stimulating glucose use by tissues and decreasing hepatic gluconeogenesis. Plasma insulin concentrations decrease with decreasing plasma concentrations of glucose and propionate. Insulin also acts as a liporegulatory hormone stimulating lipogenesis and inhibiting lipolysis. Glucagon is the primary counterregulatory hormone to insulin. The counteracting effects of insulin and glucagon therefore play a central role in the homeostatic control of glucose. A low insulin:glucagon ratio stimulates lipolysis in adipose tissue and ketogenesis in the liver. Cows in early lactation have low insulin:glucagon ratios because of low plasma glucose concentrations and are in a catabolic state. Regulation is also indirectly governed by somatotropin, which is the most important determinant of milk yield in cattle and is also lipolytic. Factors that decrease the energy supply, increase the demand for glucose, or increase the utilization of peripheral fat reserves as an energy source are likely to increase ketone production and ketonemia. There is, however, considerable cow-to-cow variation in the risk for developing clinical ketosis.

**ETIOLOGY OF BOVINE KETOsis**

It is not unreasonable to view clinical ketosis as one end of a spectrum of a metabolic state that is **common in heavily producing cows in the postcalving period**. This is because high-yielding cows in early lactation are in negative energy balance and are subclinically ketogenic as a result.

Cattle are particularly vulnerable to ketosis because, although very little carbohydrate is absorbed as such, a direct supply of glucose is essential for tissue metabolism, particularly the formation of lactose associated with milk production. The utilization of volatile fatty acids for energy purposes is also dependent on a supply of available glucose. This vulnerability is further exacerbated in the lactating dairy cow by the tremendous rate of turnover of glucose.

In the period between calving and peak lactation, the demand for glucose is increased and cannot be completely restrained. Cows will reduce milk production in response to a reduction of energy intake, but this does not follow automatically nor proportionately in early lactation because hormonal stimuli for milk production overcome the effects of reduced food intake. Under these circumstances, lowered plasma glucose concentrations result in lowered plasma insulin concentrations. Long-chain fatty acids are released from fat stores under the influence of both a low plasma insulin:glucagon ratio and the influence of high somatotropin concentration, and this leads to increased ketogenesis.

**Individual Cow Variation**

The rate of occurrence of negative energy status, and therefore the frequency of clinical ketosis cases, has increased markedly over the last 4 decades because of the increase in the lactation potential of the modern dairy cow. Because of the mammary gland’s metabolic precedence in the partitioning of nutrients, especially glucose, milk production continues at a high rate, causing an energy drain. In many individual cows, the need for energy is beyond their capacity for dry matter intake, but there is between-cow variation in risk under similar nutritional stress. Clinical ketosis is easily produced in early-lactation dairy cows by reducing the daily feed intake. Subclinical ketosis (hyperketonemia) in early-lactation dairy cows is associated with decreased dry matter intake and feeding time during the week before calving.

**Types of Bovine Ketosis**

There are many theories on the cause and biochemical and hormonal pathogenesis of ketosis, in addition to the importance of predisposing factors. Reviews of these studies are cited at the end of this disease section. In general, it can be stated that clinical ketosis occurs in cattle when they are subjected to demands on their resources of glucose and glycogen that cannot be met by their digestive and metabolic activity.

A common classification of the disease based on its natural presentation in intensively and extensively managed dairy herds, and one that accounts for the early lactational demand for glucose, a limited supply of propionate precursors, and preformed ketones or mobilized lipids in the pathogenesis, has been developed. Such a classification scheme includes the following mechanisms for ketosis, which will be discussed in turn:

- **Primary ketosis (production ketosis)**
- **Secondary ketosis**
- **Alimentary ketosis**
- **Starvation ketosis**
- **Ketosis resulting from a specific nutritional deficiency**

**Primary Ketosis (Production Ketosis)**

This is the ketosis of most herds, the so-called estate ketonemia. Primary ketosis occurs in cows in good to excessive body condition that have high lactation potential and are being fed good-quality rations but that are in a negative energy balance. There is a tendency for the disease to recur in individual animals, which is probably a reflection of variation between cows in digestive capacity or metabolic efficiency. A proportion of primary ketosis cases appear as clinical ketosis, but a much greater proportion occurs as cases of subclinical ketosis in which there are increased concentrations of circulating ketone bodies but no overt clinical signs. Affected cattle recover with correct feeding and ancillary treatment.

**Secondary Ketosis**

Secondary ketosis occurs where the presence of other disease results in a decreased food intake. The cause of the reduction in food intake is commonly the result of abomasal displacement, traumatic reticulitis, metritis, mastitis, or other diseases common to the postparturient period. A high incidence of ketosis has also been observed in herds affected with fluorosis. An unusual occurrence reported was an outbreak of acetone mia in a dairy herd fed on a ration contaminated by a low level (9.5 ppm) of lincomycin, which caused ruminal microbial dysfunction. The proportion of cases of ketosis that are secondary and their diagnosis as such are both matters of great interest because a significant proportion of all cases of ketosis in lactating dairy cattle are secondary to other disease.

**Alimentary Ketosis**

Alimentary ketosis (also called type III in some classification systems) is a result of
excessive amounts of butyrate in silage and possibly also a result of decreased food intake resulting from the poor palatability of high-butyrate silage. Silage made from succulent material may be more highly ketogenic than other types of ensilage because of its higher content of preformed butyric acid. Spoiled silage is also a cause, and toxic bio- genic amines in silage, such as putrescine, may also contribute. This type of ketosis is commonly subclinical, but it may predispose to the development of production or primary ketosis.

Starvation Ketosis
Starvation ketosis occurs in cattle that are in poor body condition and that are fed poor-quality feedstuffs. There is a deficiency of propionate and protein from the diet and a limited capacity of gluconeogenesis from body reserves. Affected cattle recover with correct feeding.

Ketosis Resulting From Specific Nutritional Deficiency
Specific dietary deficiencies of cobalt and possibly phosphorus may also lead to a high incidence of ketosis. This may be in part a result of a reduction in the intake of total digestible nutrients, but in cobalt deficiency, the essential defect is a failure to metabolize propionic acid in the TCA cycle. The problem is restricted to the cobalt-deficient areas of the world, although the occurrence of cobalt deficiency in high-producing dairy cows in nondeficient areas has been described.

There is a marked nadir in food intake around calving, followed by a gradual increase. This increase is quite variable between cows, but in the great majority of cases does not keep pace with milk yield. The net result is that high-yielding dairy cows are almost certain to be in negative energy balance for the first 2 months of lactation.

EPIDEMIOLOGY
Occurrence
Ketosis is a very common disease of lactating dairy cattle and is prevalent in most countries where intensive farming is practiced. Ketosis occurs mainly in animals housed during the winter and spring months and is rare in cows that calve on pasture. In housed or free-stalled cattle, ketosis occurs year around. The occurrence of the disease is very much dependent on management and nutrition and varies between herds. As might be expected, lactational incidence rates vary between herds, and a review of 11 epidemiologic studies showed a lactation incidence rate for ketosis that varied from 0.2% to 10.0%.

The incidence of subclinical ketosis (more correctly called hyperketonemia) is influenced by the cut-point of plasma BHB used for definition, but it is much higher than the incidence of clinical ketosis, especially in undernourished herds, and can approach 40%. Incidence can be challenging and expensive to estimate because prevalence information is usually measured. In general, the incidence of subclinical ketosis is 1.8 times the prevalence.

Animal and Management Risk Factors
There are conflicting reports on the significance of risk factors for ketosis and subclinical ketosis, which probably reflect that the disease can be a cause or effect of a number of interacting factors. The disease occurs in the immediate postparturient period, with 90% of cases occurring in the first 60 days of lactation. Regardless of the specific etiology, ketosis occurs most commonly during the first month of lactation, less commonly in the second month, and only occasionally in late pregnancy. In different studies, the median time to onset following calving has varied from 10 to 28 days, with some recent studies showing a peak prevalence of subclinical ketosis in the first 2 weeks post-calving. A prolonged previous intercalving interval increases risk.

Age. Cows of any age may be affected, but the disease increases from a low prevalence at the first calving to a peak at the fourth calving, associated with the level of milk production. Lactational incidence rates of clinical ketosis of 1.5% and 9%, respectively, were found in a study of 2415 primiparous and 4360 multiparous cows. Clinical ketosis can also recur in the same lactation.

Herd differences in prevalence are very evident in clinical practice and in the literature, with some herds having negligible occurrence. Although apparent differences in breed incidence are reported, evidence for a heritable predisposition within breeds is minimal. Feeding frequency has an effect, with the prevalence of ketosis being much lower in herds that feed a total mixed ration (TMR) ad libitum compared with herds that feed roughage and concentrate separately fed twice a day (component fed).

Body-Condition Score. There are conflicting reports on the relation between BCS at calving and ketosis, but it is very likely that studies that have found no relationship have not had many fat cows in the herds examined. Fat body condition postpartum was observed to be associated with a higher first-test-day milk yield, milk-fat-to-protein ratio of greater than 1.5, increased body-condition loss, and a higher risk for ketosis. In another study, cows with a BCS greater than 3.25 at parturition and that lost 0.75 points in BCS in the first 2 months of lactation developed subclinical ketosis. Body-condition loss during the dry period also increases risk for ketosis in the following lactation.

Season. There is no clear association with season. In some but not all summer grazing areas, a higher risk is generally observed in cattle during the winter housing period. Higher prevalence has been observed in the late summer and early winter in Scandinavian countries.

Other Interactions. There is a greater risk for the development of ketosis in cows that have an extended long dry period; those that develop milk fever, retained placenta, lameness, or hypomagnesemia; or those that have high milk production and high first milking colostrum volume. Cows with twins are also at risk for ketosis in the terminal stages of pregnancy. There is a bidirectional relationship between risk for displaced abomasum and risk for ketosis, but in a field study of 1000 cows in 25 herds, cows that had a serum BHB concentration greater than 1.4 mmol/L in the first 2 weeks of lactation had odds of 4.1 that a displaced abomasum would be diagnosed 1 to 3 weeks later. In another study of 1010 cows, a serum BHB concentration of 1.5 mmol/L or greater in the first 2 weeks of lactation was found to be associated with a threefold increase in ketosis or displaced abomasum. Interestingly, cows with increased blood BHB concentration immediately before surgical correction of left-displaced abomasum have increased longevity within the herd, compared with cattle with BHB concentrations within the reference interval.

Economic Significance
Clinical and subclinical ketosis are major causes of loss to the dairy farmer. In rare instances the disease is irreversible and the affected animal dies, but the main economic loss results from the loss of production while the disease is present, the possible failure to return to full production after recovery, and the increased occurrence of periparturient disease. Both clinical and subclinical ketosis are accompanied by decreased milk yields; lower milk protein and milk lactose; increased risk for delayed estrus and lower first-service conception rates; lower pregnancy rates; increased intercalving intervals; increased risk of cystic ovarian disease, metritis, and mastitis; and increased involuntary culling. The estimated economic loss from a single case of subclinical ketosis was US$117 in 2015, and the estimated average total cost per case of subclinical ketosis was $289 after considering the costs of displaced abomasum and metritis attributed to hyperketonemia.

PATHOGENESIS
Bovine Ketosis
The principal metabolic disturbances observed, hypoglycemia and ketonemia, may both exert an effect on the clinical syndrome. However, in the experimental disease in cattle, it is not always clear what determines the development of the clinical signs in cases that convert from subclinical to clinical
ketosis. In many cases, the severity of the clinical syndrome is proportional to the degree of hypoglycemia, and this, together with the rapid response to parenterally administered glucose in cattle, suggests hypoglycemia as the predominant factor. This hypothesis is supported by the development of prolonged hypoglycemia and a similar clinical syndrome to that of ketosis, after the experimental IV or SC injection of insulin (2 U/kg BW).

However, in most field cases the severity of the clinical syndrome is also roughly proportional to the degree of ketonemia. This is an understandable relationship because ketone bodies are produced in larger quantities as the deficiency of glucose increases. However, the ketone bodies are thought to exert an additional influence on the clinical signs observed; for instance, acetocetic acid is known to be toxic and probably contributes to the terminal coma in diabetes mellitus in humans.

The nervous signs that occur in some cases of bovine ketosis are thought to be caused by the production of isopropanol, a breakdown product of acetone in the rumen, although the requirement of nervous tissue for glucose to maintain normal function may also be a factor in these cases. A reasonable explanation for the development of nervous ketosis is that a rapid increase in plasma acetone concentration in an animal that has an active rumen flora leads to a rapid increase in ruminal acetone concentration. The acetone is metabolized by rumen microflora to isopropanol, which is then absorbed into the bloodstream, potentially leading to neuropsychologic abnormalities. This mechanism is consistent with observations that nervous signs of ketosis are more common in cattle with severe ketosis that is rapidly induced.

Spontaneous ketosis in cattle is usually readily reversible by treatment; incomplete or temporary response is usually a result of the existence of a primary disease, with ketosis present only as a secondary development, although fatty degeneration of the liver in protracted cases may prolong the recovery period. Changes in ruminal flora after a long period of anorexia may also cause continued impairment of digestion.

Immunosuppression has been demonstrated with energy deficiency and ketosis. The higher susceptibility of ketogenic postpartum cows to local and systemic infections may be related to impairment of the respiratory burst of neutrophils that occurs with elevated plasma concentrations of BHB.

**CLINICAL FINDINGS**

Two major clinical forms of bovine ketosis are described—wasting and nervous—but these are the two extremes of a range of syndromes in which wasting and nervous signs are present in varying degrees of prominence.

The **wasting form** is the most common of the two and is manifest with a gradual but moderate decrease in appetite and milk yield over 2 to 4 days. In component-fed herds, the pattern of appetite loss is often very specific in that the cow first refuses to eat grain, then ensilage, but may continue to eat hay. The appetite may also be depraved. Body weight is lost rapidly, usually at a greater rate than one would expect from the decrease in appetite. Farmers usually describe affected cows as having a “woody” appearance because of the apparent wasting and loss of cutaneous elasticity presumably resulting from disappearance of subcutaneous fat. The feces are firm and dry, but serious constipation does not occur. The cow is moderately depressed and is quieter than usual. The disinclination to move and to eat may suggest the presence of mild abdominal pain, but localized pain cannot be detected via abdominal palpation.

The temperature and the pulse and respiratory rates are normal, and although the ruminal movements may be decreased in amplitude and number, they are within the normal range unless the course is of long duration, in which case they may virtually disappear. The characteristic sweet odor of ketones is detectable on the breath and often in the milk, but people vary in their ability to detect ketones on the breath (specifically the volatile ketone, acetone).

Very few affected animals die, but without treatment the milk yield falls; although spontaneous recovery usually occurs over about a month, as equilibrium between the drain of lactation and food intake is established, the milk yield is never fully regained. The fall in milk yield in the wasting form may be as much as 25%, and there is an accompanying sharp drop in the solids-not-fat content of the milk. In the wasting form, nervous signs may occur in a few cases, but they rarely comprise more than transient bouts of staggering and partial blindness.

In the **nervous form** (nervous ketosis), signs are usually bizarre and begin quite suddenly. The syndrome is suggestive of delirium rather than of frenzy, and the characteristic signs include the following:

- Walking in circles
- Straddling or crossing of the legs
- Head pushing or leaning into the stanchion
- Apparent blindness
- Aimless movements and wandering
- Vigorous movements with salivation
- Hyperesthesia

Hyperesthesia may be evident, with the animal bellowing on being pinched or stroked. Moderate tremor and tetany may be present, and there is usually an incoordinate gait. The nervous signs usually occur in **short episodes** that last for 1 or 2 hours and may recur at intervals of about 8 to 12 hours. Affected cows may injure themselves during the nervous episodes. Surgical correction of displaced abomasum in cows exhibiting some signs consistent with nervous ketosis should be delayed until their energy status has been evaluated and treatment instituted, if indicated.

**Subclinical Ketosis (Hyperketonemia)**

Subclinical ketosis is defined as an increase in blood/plasma/serum BHB above the normal reference range or ketonuria in a cow without detectable clinical signs of disease. Many cows that are in negative energy balance in early pregnancy will have ketonuria without showing clinical signs, but they
Cows have plasma BHB concentrations less than 1.0 mmol/L; cows with subclinical ketosis have blood or plasma/serum concentrations greater than 1.0, 1.2, or 1.4 mmol/L (the cut-point varies depending on the study, analytical method, and whether blood or plasma is analyzed). Different cut-points have been proposed for serum BHB concentration in the first week postpartum (1.0 mmol/L) and the second week postpartum (1.4 mmol/L); this may be attributable to blood BHB concentrations being highest at 8 days in milk. In general, because the cut-point for the diagnosis of subclinical ketosis should be based on a detectable effect on decreasing milk production or an increased risk of adverse health events, a consensus is developing around the use of serum/plasma BHB concentration greater than 1.0 mmol/L as the cut-point for subclinical ketosis based on the association with impaired reproductive performance and increased risk of developing a displaced abomasum, puerperal metritis, or clinical ketosis.

Cows with clinical ketosis usually have serum/plasma BHB concentrations in excess of 2.5 mmol/L, with values rarely reaching 10.0 mmol/L. Plasma BHB shows some diurnal variation in cows fed twice daily, with peak concentrations occurring approximately 4 hours after feeding and higher concentrations in the morning than in the afternoon. This diurnal variation is not as prominent in cows fed a total mixed ration and should be clinically regarded as a reference for monitoring ketosis.

**Milk and Urine Cow-Side Tests**

Cow-side tests have the advantage of being inexpensive and giving immediate results, and they can be used as frequently as necessary. A minor source of error is that the concentration of ketone bodies in these fluids will depend not only on the ketone concentration of the plasma, but also on the amount of urine excreted or on the milk yield. Milk concentration of ketones is less variable, easier to collect, and may give fewer false negatives in cows with subclinical ketosis.

Milk and urine ketone concentrations have been traditionally detected by the reaction of acetoacetate with sodium nitroprusside and can be interpreted in a semiquantitative manner based on the intensity of the reaction. The nitroprusside reaction detects both acetoacetate and acetone, but it is much more sensitive to acetoacetate than acetone; the latter is only detected when acetone concentrations are greater than 600 mmol/L, which represents a supraphysiologic concentration. As a consequence, the nitroprusside test functions as a semiquantitative test of acetoacetate concentration and should be clinically regarded as a test of acetoacetate and not acetone. Several products are available commercially as strips or test powders and are commonly accompanied by a color chart that allows a classification of acetoacetate concentration in grades such as negative, trace (5 mg/dL), small (15 mg/dL), moderate (40 mg/dL), or large (>80 mg/dL), based on the intensity of the color of the reaction. Milk powder tests are not sufficiently sensitive for detection of subclinical ketosis (report too many false negatives), and urine tests are not sufficiently specific (report too many false positives).

**Milk Testing.** The sensitivity and specificity of the nitroprusside powder test with milk in various studies is reported as 28% to 90% and 96% to 100%, respectively. Currently, a milk strip test detecting the concentration of BHB in milk is available and is graded on the concentration of BHB. In different studies, milk BHB has a reported sensitivity and specificity of 58% to 96% and 69% to 99%, respectively. These variations are in part a result of the use of different plasma BHB reference values (1.2 and 1.4 mmol/L) for designation of subclinical ketosis and different statistical methods for analysis. Somatic cell counts in milk greater than 1 million cells/mL will cause an elevation in reading of both the BHBA strip test and the nitroprusside tests.

**Urine Testing.** A nitroprusside tablet has a reported sensitivity and specificity of 100% and 59%, respectively, compared with serum BHB concentrations above 1.4 mmol/L; a nitroprusside strip test has a reported

sensitivity and specificity of 78% and 96%, respectively, with a urine cut-point corresponding to "small" on the color chart or 49% and 99%, respectively, with a urine cut-point corresponding to "moderate" on the color chart. BHB test strips when used with urine have a reported sensitivity and specificity of 73% and 96%, respectively, at a urine cut-point of 0.1 mmol/L. BHB and 27% and 99%, respectively, at a urine cut-point of 0.2 mmol/L BHB. Urinary ketone concentrations are more closely related to plasma ketone concentrations than are milk BHB and acetocetate concentrations. Moreover, urine acetocetate concentration appears superior to milk BHB concentration in diagnosing ketosis.17

Milk-Fat-to-Protein Ratio. Milk-fat concentration tends to decrease, and milk protein concentration tends to decrease, during postpartum negative energy balance. A fat-to-protein ratio greater than 1.5 in first-day test milk is indicative of a lack of energy supply in the feed and of risk for ketosis and provides a similar test sensitivity (Se = 0.63) for detecting subclinical ketosis as does milk BHB concentration (Se = 0.58).17 Milk production in multiparous animals is also separately associated with postpartum negative energy balance.18

Clinical Chemistry and Hematology. White and differential cell counts are variable and not of diagnostic value for ketosis. There are usually elevations of liver enzyme activity in plasma/serum, but liver function tests are within the normal range. Liver biopsy is the only accurate method to determine the degree of liver damage.

Plasma concentrations of NEFAs and total bilirubin are elevated in ketosis, with mean NEFA concentrations increasing above 0.3 mmol/L from 3 days before parturition to approximately 0.7 mmol/L from 0 to 9 days in milk, after which time plasma NEFA concentration gradually decreases.12 The increase in bilirubin is attributed, in part, to hepatic dysfunction; however, bilirubin is not a sufficiently sensitive indicator to assess the extent of fat mobilization and liver function in cows with ketosis. Plasma cholesterol concentration is typically decreased for the stage of lactation; the decrease in cholesterol is a result of decreased hepatocyte secretion of very-low-density lipoproteins (VLDLs), which are cholesterol rich, or increased mammary uptake of cholesterol relative to cholesterol availability. After secretion, VLDLs are processed in plasma to intermediate-density lipoproteins by hydrolysis of triglycerides.19 Intermediate-density lipoproteins are then metabolized in plasma to cholesterol-rich low-density lipoproteins that carry cholesterol to peripheral tissues, including the mammary gland.10,12 A clinically significant proportion of lactating dairy cattle with ketosis have low plasma cortisol concentrations;21 although the mechanism has not been determined, it is possible that decreased cholesterol availability negatively affects cortisol synthesis.

Liver glycogen levels are low, and the glucose tolerance curve may be normal. Volatile fatty acid levels in the rumen are much higher in ketotic than in normal cows, and the ruminal concentrations of butyrate are markedly increased relative to acetate and propionate acids. There is a small but significant drop in serum calcium concentrations (down to about 9 mg/dL [2.25 mmol/L]), probably as a result of decreased dry matter intake in lactating dairy cattle relative to the level of milk production.

Plasma and urine metabolic profiling shows promise as a means of differentiating cattle with clinical ketosis and subclinical ketosis from healthy cattle at the same stage of lactation. Twenty-five plasma metabolites and 11 urine proteins have been identified to differ between these three groups. Differences include changes in plasma amino acid concentrations that may reflect differences in feed intake relative to milk production or altered metabolic pathways and changes in urine polypeptide concentrations that may reflect decreased immune responsiveness.

Necropsy Findings

The disease is not usually fatal in cattle, but fatty degeneration of the liver and secondary changes in the anterior pituitary gland and adrenal cortex may be present.

Differentiation Diagnosis

Cattle

The clinical picture is usually too indefinite, especially in cattle, to enable a diagnosis to be made solely on clinical grounds. General consideration of the history, with particular reference to the time of calving, and the feeding program, and biochemical examination to detect the presence of hypoglycemia, ketonemia, and ketonuria are necessary to establish a diagnosis.

Wasting form:

- Abomasal displacement
- Traumatic reticulitis
- Primary indigestion
- Cystitis and pyelonephritis

Nervous form:

- Rabies
- Hypomagnesemia
- Bovine spongiform encephalopathy

Treatment

In cattle, a number of effective treatments are available for ketosis, but in some affected animals, the response is only transient; in rare cases, the disease may persist and cause death or necessitate slaughter of the animals. Most of these cases are secondary, and failure to respond satisfactorily to treatment is a result of the primary disease. Specific treatment for subclinical ketosis is usually not applied on an individual basis, but nutritional and management issues should be investigated whenever a large proportion of early-lactation cows are diagnosed with subclinical ketosis.

The rational treatment in ketosis is to relieve the need for glucose formation from tissues and allow ketone-body utilization to continue normally. Theoretically, the simplest means of doing this is by the administration of glucose replacement therapy. The effect of the administration of glucose is complex, but it allows the reversal of ketogenesis and the establishment of normal patterns of energy metabolism. Ideally, treatment should be at an early stage of the disease to minimize loss, and with subclinical ketosis this requires biochemical testing.

Replacement Therapy

Glucose (Dextrose)

The IV injection of 500 mL of a 50% solution of glucose results in transient hyperglycemia, increased insulin and decreased glucagon secretion, and reduced plasma concentration of NEFAs. Glucose administration affects a marked improvement in most cows, but relapses occur commonly unless repeated treatments are used. This is probably a result of the transience of the hyperglycemia (3 to 4 hours) or insufficient dosing—the dose required varies directly with the amount of lactose being lost in the milk. Contrary to widespread belief, very little of the administered glucose is lost to urinary excretion (<10%).19 SC injections of hypertonic glucose prolong the response, but they are not recommended because they cause discomfort, and large unsightly swellings, which often become infected, may result. Intraperitoneal injections of 20% solution of dextrose have also been used, but they are not recommended because of the risk of infection.

Other Sugars

Other sugars, especially fructose, either alone or as a mixture of glucose and fructose (invert sugar), and xylitol, have been used in an effort to prolong the response, but idiosyncratic responses to some preparations, in the form of polyneuropathy, muscle tremor, weakness, and collapse, can occur while the injection is being given.

Propylene Gylcol and Glycerine/Glycerol

To overcome the necessity for repeated injections, propylene glycol can be administered as a drench. The traditional dose is 225 mL twice daily for 2 days, followed by 110 mL daily for 2 days to cattle, but higher volumes are also used for larger cattle (a typical treatment protocol in North America is 300 mL PO daily for 5 days). Some of the administered propylene glycol is metabolized to propionate in the rumen and absorbed, whereas some of the propylene glycol is absorbed
directly across ruminal epithelium and metabolized by the liver. Propylene glycol (200 to 700 g daily), or salts of propionate, can be administered in the feed and give good results. Administration in feed is preferred by some because this method avoids dangers of aspiration with drenching; however, cows not used to its inclusion in the feed may show feed refusal. Studies also suggest that drenching of propylene glycol provides a more beneficial response than including the same amount in a total mixed ration; the bolus effect of propionate production appears to be more beneficial than a steady-state increase as a result of a bolus increase in plasma insulin concentration. It is recommended that for best results, dosing with propylene glycol should be preceded by an IV injection of glucose.

Parenteral infusions of glucose solutions and the feeding of glycerol depress the fat content of milk, and the net saving in energy may favorably influence response to these drugs. Glycerol and propylene glycol are not as efficient as glucose because conversion to glucose utilizes oxaloacetate. Propylene glycol is absorbed directly from the rumen and acts to reduce ketogenesis by increasing mitochondrial citrate concentrations; its metabolism to glucose occurs via conversion to pyruvate, with subsequent production of oxaloacetate via pyruvate carboxylase.

**Other Glucose Precursors**

Because of its glucogenic effect, sodium propionate is theoretically a suitable treatment, but when administered in 110- to 225-g (200 to 400 g) doses daily, the response in cattle is often very slow. Lactates are also highly glucogenic, but both calcium and sodium lactate (1 kg initially, followed by 0.5 kg for 7 days) and sodium acetate (110 to 500 g/d) have given less satisfactory results than those obtained with sodium propionate. Ammonium lactate (200 g for 5 days) has, however, been used extensively, with reported good results. Lactose, in whey or in granular form in the diet, can increase dry matter intake, but it also increases ruminal butyrate concentration and plasma BHb concentrations.

**Hormonal Therapy**

**Glucocorticoids.** The efficiency of glucocorticoids in the treatment of bovine ketosis has been demonstrated in both experimental and field cases. The observation that a clinically significant proportion of lactating dairy cattle with ketosis have low plasma cortisol concentrations provides support for glucocorticoid administration. Hyperglycemia occurs within 24 hours of glucocorticoid administration and appears to result from a repartitioning of glucose in the body rather than from gluconeogenesis. Historically, many glucocorticoid preparations have been used successfully, but current drugs are more potent, require lower dosage, and have fewer side effects. A hyperglycemic state is produced for 4 to 6 days in ketotic cows given 10 mg of dexamethasone 21-isonicotinate, and other preparations that have a shorter duration of action, such as dexamethasone sodium phosphate (40 mg) and flumethasone (5 mg), are also used. Dexamethasone 21-isonicotinate (20 to 25 mg IM) decreases whole-body insulin sensitivity and affects glucose and lipid metabolism; it decreases liver fat content in early-lactating dairy cows with surgically corrected left-displaced abomasum. Label regulations vary between countries; in general, the recommendations of the manufacturer with regard to glucocorticoid use and dosage should be followed. Profound hypokalemia with high case fatality is a potential sequel to prolonged repeated therapy of ketosis with isoulpredone acetate, which has both glucocorticoid and mineralocorticoid activity. For this reason, only one treatment of isoulpredone acetate is recommended for cows with ketosis. Response of cows with primary ketosis to treatment with corticosteroids and IV glucose is superior to therapy with corticosteroids or IV glucose alone, with fewer relapses.

**Insulin** facilitates cellular uptake of glucose, suppresses fatty acid metabolism, and stimulates hepatic gluconeogenesis. Insulin is administered in conjunction with either glucose or a glucocorticoid and may be of particular value in early-onset cases of ketosis that are unresponsive to glucose or corticosteroid therapy, but it is not commonly used. The dose of protamine zinc insulin is 200 to 300 IU per animal (depending on body weight) administered SC every 24 to 48 hours as required. It should be recognized that endogenous insulin is released in all lactating dairy cattle administered 500 mL of 50% dextrose, although to a lower extent in ketotic cattle because they have a lower peak plasma glucose concentration following IV infusion of glucose or propionate; consequently, IV dextrose administration should always be considered as a dual treatment of glucose and insulin.

**Anabolic steroids** have also been used for treatment of lactational ketosis and ketosis in late pregnant cows that are overfat, stressed, or have twin fetuses. Experimentally, 60 mg and 120 mg of trenbolone acetate are effective as single injections, but no extensive field trials are recorded, and the drug is banned for use in food animals in most countries.

**Miscellaneous Treatments.** Vitamin B12 and cobalt are indicated in regions where cobalt deficiency is a risk factor for ketosis. Cobalt is sometimes administered to cattle with ketosis in regions where cobalt deficiency does not occur, but the therapeutic value is not proven. Cyanocobalamin (vitamin B12, 1 to 4 mg IV daily) in a combined formulation with butaphosphan has strong evidence supporting its role in normalizing energy status in early-lactation dairy cows when administered to dairy cattle before or around parturition. Cyanocobalamin is essential for gluconeogenesis from propionate, and a theoretical argument can be made for the administration of cyanocobalamin for ketotic dairy cattle being treated for ketosis. It is also thought that high-producing dairy cows in early lactation have a relative or actual deficiency of cyanocobalamin. Cysteine (a biological precursor of coenzyme A) and also sodium fumarate have been used to treat cases of the disease. Reported results were initially good, but the treatment has not been generally adopted. The recommended dose rate of cysteine is 750 mg IV for three doses at 1- to 3-day intervals.

**Glucagon,** although ketogenic, is strongly gluconeogenic and glycogenolytic, and glucagon concentrations are decreased in the plasma of fat cows at calving and cows with ketonemia. Glucagon could be of value in prevention and therapy, but it would require a prolonged delivery system because it has a very short physiologic half-life and its effects following a single injection are short-lived.

**Control**

- Monensin (11 to 22 g/ton of mixed ration on a 100% dry matter basis; oral administration of a controlled-release capsule delivers 335 mg/day for 95 days) (R-1)
- Propylene glycol (300 to 500 mL daily, PO) (R-1)
- Rumen-protected choline (15g daily, PO, from 25 days precalving to 80 days postcalving) (R-2)
- Cyanocobalamin (vitamin B12, 1 to 4 mg IV, daily for 2 to 6 treatments before or at calving) (R-2)
- Isoflupredone (20 mg, IM, once), with or without insulin (100 U, SC) (R-3)

**CONTROL**

The control of clinical ketosis is integrally related to the adequate nutrition of the cow in the dry and lactating periods. This encompasses details such as the following:
• Dry matter intake
• Fiber digestibility
• Particle size distribution
• Energy density
• Fat incorporation in early lactation rations
• Protein content
• Feeding systems
• Rumen size
• Other factors better covered in texts on nutrition

It is difficult to make general recommendations for the control of the ketosis because of the many conditions under which it occurs, its probable multiple etiology, and feeding systems that vary from those that feed components separately to those that feed total mixed rations. Cows neither should have been starved nor be overfat at calving. Careful estimation of diets by reference to feed value tables is recommended, and detailed recommendations on diet and management are available, with the caveat that planned rations can deviate from feed bunk rations, and feed bunk dry matter and actual dry matter intake may not be the same. Too low a feeding frequency and the feeding of concentrates separate from roughage rather than as a total mixed ration can lead to an increase in rates of ketosis.

In the United States, dry cows are typically divided into two groups: far-off and close-up cows. Far off cows are generally fed to National Research Council (NRC) dry-cow feeding guidelines, and close-up cows are given an acidogenic ration that decreases to National Research Council dry-close-up cows. Far off cows are generally fed cattle in early lactation at doses varying from

Monensin is approved for continuous administration (>14 days) to dairy cattle in the United States at 185 to 660 (mg/head)/day monensin to lactating cows or 115 to 410 (mg/head)/day monensin to dry cows. To accomplish this, monensin is approved to be fed at 11 to 22 g/t (g/head) of total mixed ration on a 100% dry matter basis, at a daily per-cow cost of about 2 to 4 cents. Monensin is also approved for use in the United States as part of a component feeding system at 11 to 400 g/t (g/head) (as is basis); this includes application as a “top dress,” where a small amount of feed is added to a ration.

In some countries, monensin can be administered orally as a controlled-release capsule to cattle 2 to 4 weeks before calving. The capsule contains 32 g of monensin and releases approximately 335 mg monensin a day for 95 days. This product is effective and practical for a variety of feeding systems, and approximately 18% of dairy herds in Canada are administering monensin by controlled-release capsule.

Corticosteroids
Isolupredone acetate (20 mg, IM, once) was not effective in preventing subclinical ketosis in early-lactation dairy cows, and it actually increased the likelihood of subclinical ketosis.

Ancillary Agents
A commercially available injectable product containing cyanocobalamin (vitamin B12, 1 to 4 mg daily IV) in a combined formulation with butaphosphan is effective in normalizing energy status when administered to dairy cattle 2 to 6 times before or around parturition. The administration of cyanocobalamin and butaphosphan may be most beneficial in cows at increased risk of developing ketosis, such as older cows, over-conditioned cows, or those experiencing dystocia or metritis. Phosphorus may be limiting in early lactation, based on low liver phosphorus content in dairy cattle. It is not clear whether additional phosphorus mitigates the reduction in hepatic phosphorus content.

Rumen protected choline (15 g/day) fed daily starting 25 days before calving and continuing to 80 days after calving decreased the incidence of clinical ketosis and improved the health of lactating dairy cows. Choline
is a precursor for phosphatidylcholine, which is thought to be rate limiting in early lactation; phosphatidylcholine deficiency is associated with impaired lipid metabolism. Niacin is antilipolytic and induces increases in blood glucose and insulin, but there is conflicting evidence that niacin given in the feed has a beneficial effect on subclinical ketosis in cattle. It has been suggested that niacin should be supplemented from 2 weeks before parturition to 12 weeks postpartum.

**General Control**

**Herd Monitoring.** There is currently no consensus as to the optimal monitoring program for ketosis and subclinical ketosis in lactating dairy cattle, and consequently a variety of monitoring programs have been proposed. Challenges with developing optimal monitoring programs are the herd size (through the influence on the eligible numbers of animals available to be tested), ease of testing, cost of the test, and test sensitivity and specificity. In addition, the goals of the monitoring program need to be defined; typically they are either to monitor the adequacy of the diet relative to the level of milk production (i.e., the magnitude of negative energy balance in early lactation) or to identify animals to receive a standard treatment protocol, such as daily oral propylene glycol drenching. The optimal time for testing appears to be cows 3 to 9 days in milk because cows that are hyperketonemic at this stage of lactation are at highest risk for subsequent negative production and health effects, with the incidence and prevalence of subclinical ketosis occurring on day 5 of lactation. A recent modeling approach utilizing 13,000 cows from 833 dairy farms in North America and Europe suggested that testing cows twice weekly from 3 to 9 days in milk was the most cost effective strategy when the subclinical ketosis incidence was between 15% and 50%; below an incidence of 15% it was not economical to test, and above 50% all cows should be treated without testing. In addition, whenever the subclinical ketosis incidence increased to above 15%, a variety of testing and treatment protocols are economically beneficial.

The six most valuable and practical indices for monitoring negative energy balance are urine acetoadetate concentration, blood BHBP concentration, blood glucose concentration, body-condition score, back-fat thickness determined ultrasonographically, and milk-fat-to-protein ratio. The first five indices can be obtained cow side and at no cost or relatively low cost, although determining the blood BHBP concentration costs approximately 5 to 10 times that of the first two tests and requires a blood sample. The milk-fat-to-protein ratio is readily obtained from individual monthly test data and is more highly correlated with energy balance than plasma BHBP or glucose concentration.

This should be coupled with body-condition scoring or back-fat thickness to monitor the efficacy of the nutritional program. Plasma NEFA concentration is an excellent monitoring test of negative energy balance, but it is currently too expensive for routine herd monitoring, and an easy-to-use cow-side test is not available.

Urine testing using the nitroprusside test for acetoadetate is the simplest of the cow-side tests, and despite some reports that urine samples are difficult to obtain from all cattle, urine is easily obtained from more than 90% of cattle using the following standardized technique. First, stimulation of the perineum to obtain a urine sample must be the first part of the examination of the cow and ideally should be performed without the cow being aware that the veterinarian is present. Second, never hold the tail while stimulating the perineum because tail holding alerts the cow to the presence of the veterinarian, and it is not needed because cattle never urinate on their tails when posturing to urinate. Third, obtain urine samples in the normal environment of the animal; because cattle urinate on average five times per day, urine samples are easily obtained on recumbent cattle that are gently encouraged to stand.

Blood BHBP testing has become very popular because of the availability of low-cost point-of-care meters. Despite this, it must be recognized that obtaining a blood sample is more complicated than obtaining a urine sample, and that the cost, although low, is much higher than that for urine acetoadetate or blood glucose testing. Moreover, serum BHBP concentration is correlated with energy balance in a similar manner to plasma glucose concentration. Automated monitoring by in-line measurements of ketone bodies in milk has been studied and may be of particular value in large dairies. BHBP is proposed as the candidate because it is the most robust in milk, and where cows are fed a total mixed ration, it is not subject to significant diurnal variation. Milk BHBP concentration can be measured in real-time with a fluorometric method that requires no pretreatment of the milk.

Biochemical monitoring of herds for subclinical ketosis and adequacy of periparturient feeding can be conducted using blood glucose estimations on a sample of cows in their second week of lactation. Plasma glucose concentrations below 45 mg/dL (2.4 mmol/L) suggest subclinical ketosis. For individual cows, blood glucose estimations should be done at about 14 days after calving. This method of monitoring is inexpensive using widely available point-of-care devices.

**FATTY LIVER IN CATTLE**

**FAT-MOBILIZATION SYNDROME, FAT-COW SYNDROME, HEPATIC LIPIDOSIS, PREGNANCY TOXEMIA IN CATTLE**

Fatty liver (hepatic lipidosis) is an important metabolic disease of dairy cows in early lactation and is associated with decreased health status and reproductive performance.
**ETIOLOGY**

Fatty liver is caused by the mobilization of excessive quantities of fat from body deposits to the liver. It develops when the hepatic uptake of lipids exceeds the oxidation and secretion of lipids by the liver. Excess lipids are stored as triacylglycerol in the liver, and excessive lipid in hepatocytes is associated with decreased metabolic function of the liver. Fatty liver occurs because of a sudden demand of energy in the immediate postpartum period in well-conditioned lactating dairy cows. Fatty liver also occurs because of a sudden deprivation of feed in fat pregnant beef cattle, and is especially severe in those bearing twins. The disease is an exaggeration of what is a common occurrence in high-producing dairy cows that are in a state of negative energy balance in early lactation. A substantial drop in voluntary dry matter intake is initiated in late pregnancy and continues into early lactation. This decrease has traditionally been interpreted as caused by physical constraints in the abdomen as a result of the enlarging gravid uterus, but this purported mechanism appears to have been overemphasized. The decline in dry matter intake coincides with changes in reproduction status, changes in fat mass, and metabolic changes in support of lactation, and the associated metabolic signals are likely to play an important role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, and intrahepatic lipids, including triglycerides, free fatty acids, and cholesterol. The degree of fat mobilization, but the degree of negative energy balance in early lactation is critical.

**EPIDEMIOLOGY**

**Occurrence and Incidence**

Fatty infiltration of the liver is common in high-producing dairy cattle from a few weeks before and after parturition and is associated with several periparturient diseases and an increase in the calving-to-conception interval. In dairy cows, fatty liver occurs primarily in the first 4 weeks after calving when up to 50% of all cows have some accumulation of triacylglycerol in the liver. A severe form of fatty infiltration of the liver immediately before or after parturition is known as the fat-mobilization syndrome, fat-cow syndrome, or pregnancy toxaemia of cattle, and it can be highly fatal. In beef cattle, the disease occurs most commonly in late pregnancy when the nutrient intake is decreased in cattle that were previously well fed and in good body condition. In a field study, the percentage of cattle dying or being culled because of disease was affected by the amount of hepatic triacylglyceride: 15%, 31%, and 42% for cattle with mild, moderate, and severe hepatic lipidosis, respectively. Outbreaks of the disease occurred in dairy herds in which up to 25% of all cows were affected, with a case-fatality rate of 90%. Cattle have been classified into three groups on the basis of liver fat content determined histologically 1 week after parturition. Less than 20% lipid corresponds to less than 50 mg/g liver by weight; 20% to 40% lipid, 50 to 100 mg/g liver; and greater than 40% represents more than 100 mg/g liver. These concentrations correspond to mild, moderate, and severe cases of fatty infiltration, respectively. Cows with less than 20% lipid in the liver 1 week after calving are considered normal, and those with more than 20% are considered to have a fatty liver. About 30% of high-yielding dairy cows in the United Kingdom are considered to have a fatty liver 1 week after calving. Clinical evidence of hepatic disease may not occur consistently until liver lipid concentrations are in the range of 35% to 45% or more.

**Risk Factors**

**Host Factors**

Fatty infiltration of the liver is part of a generalized fat-mobilization syndrome that occurs in early lactation, particularly in high-yielding dairy cows, as milk production outstrips appetite and body reserves are used to meet the energy deficit. In about 30% of high-producing cows, fatty infiltration in the liver is severe and is associated with reversible but significant effects on liver structure and function. In some populations of cows, the incidence of fatty liver is much lower and insignificant. Diseases that occur commonly in early lactation predispose to fatty liver include ketosis, left-side displacement of the abomasum, mastitis, retained fetal membranes, milk fever, and downer-cow syndrome. Any disease of early lactation that affects appetite and voluntary intake can contribute to fatty liver.

The deficit occurs because dietary intake cannot meet the energy requirements for the high yield. Peak yields of milk are reached 4 to 7 weeks after calving, but the highest levels of voluntary feed intake are not reached until 8 to 10 weeks after calving. As a result of the energy deficit, the cow mobilizes body reserves for milk production and may lose a large amount of body weight. The BCS at calving can have a direct effect on the health, milk yield, and fertility of cows. It represents the cumulative effects of the dry period, the BCS at drying off, and the loss of body condition during the dry period. The risk of retained placenta may be greater for cows underconditioned at drying, whereas cows that lost more body condition during the dry period may be more affected by both retained placenta and metritis; the two effects are independent of each other. The risk of ketosis is increased in cows overconditioned at calving, which may be a result of a long dry period. Cows calving at a higher BCS produced more milk, fat, and protein in the first 90 days of lactation, and the effect was most pronounced for milk-fat content. Cows with a higher BCS at calving were less prone to anestrus, but they did not conceive more successfully to first service. A reduction of 6 open days in primiparous cows was estimated for each additional unit of BCS at calving. Multiparous cows that lose more body condition during the dry period are more prone to inactive ovaries and are more likely to be open 150 days after calving in the next lactation. Dairy cows with abnormally long dry periods also have a tendency to become
obese and develop the fatty liver syndrome of parturition. The feeding of dairy cows in large groups, as in loose housing systems, has been associated with an increase in the incidence of the disease. The disease has occurred in pregnant heifers within 31 days after being turned out onto grass.

The disease can occur in nonlactating dairy cows by the imposition of a partial-starvation diet in late pregnancy in an attempt to reduce the body weight of cows that are considered to be too fat. Changing the diet of pregnant beef cows from silage to straw in an attempt to reduce their body weight and the incidence of dystocia has resulted in outbreaks of the disease.

In beef cattle in North America, the severe form of the disease, pregnancy toxemia, is seen most commonly in the last 6 weeks of pregnancy in cows that are fat and pregnant with twins. The affected cows are usually well fed until late pregnancy, when an unexpected shortage of feed occurs, or the cows are too fat and cannot consume sufficient low-energy feed to meet the demands of pregnancy. Under usual circumstances, the disease in beef cattle occurs sporadically: the morbidity is about 1%, but the mortality is usually 100%.

Pregnancy toxemia of calf has occurred in pregnant beef cattle in Australia and the United Kingdom. First-calf heifers were more commonly affected than older cows, and most were in late pregnancy (7 to 9 months) or had just recently calved. Cows pregnant with twins are particularly susceptible.

Genetics of Lipid Mobilization

Cows generally mobilize body lipid reserves in early lactation and regain these reserves during subsequent pregnancy. Lipid mobilized from body reserves makes a substantial contribution to the energetic cost of milk production in early lactation. It is usually assumed that this mobilization of body energy reserves is entirely a response to a deficit in feed energy intake relative to milk energy output. This implies that increasing the energy content of the feed being offered would decrease body energy mobilization in early lactation. A number of studies indicate that this is not always the case. It has been proposed that mobilization of body reserves in early lactation and the subsequent gain in body reserves during pregnancy are to a large extent genetically driven. Genetically driven body-lipid change is defined as that which would occur in cows kept in an environment that was in no way constraining. It then follows that environmentally driven body-lipid change is defined as that which occurs in response to an environment that is constraining. The rationale and evidence for genetically driven body-lipid change have their basis in evolutionary considerations and in the changes in lipid metabolism throughout the reproductive cycle.

Environmental and Dietary Factors

In North America, the introduction of the system of challenge feeding of dairy cows was associated with an increased incidence of fatty liver. The overall effect of the system is to provide excess energy in the diet during late pregnancy or during the dry period generally. The diets fed may contain a high percentage of the cereal grains, corn ensilage, or brewer’s grains. In this system, high-energy rations are fed beginning a few weeks before parturition. The total daily amount of feed is increased by regular increments to reach a high level at parturition and peak levels to coincide with the peak in the lactation curve several weeks after parturition. This resulted in some excessively fat cows at the time of parturition, when energy demands are high. The disease has also occurred in dairy cows that were fed excessive amounts of high-energy rations throughout the dry period. In dairy herds, fatty liver syndrome has also been associated with an increase in the incidence of milk fever, ketosis, and left-sided displacement of the abomasum, all of which are much more difficult to treat successfully because of the fatty liver.

Overfeeding during the dry period predisposes cows to accumulate fat in adipose tissue during the prepartum period. Before parturition, adipose tissue from overfed cows has higher rates of esterification than the adipose tissue of cows fed a restricted energy intake. In the fatty livers of these overfed cows, the rate of gluconeogenesis is not optimal, which results prolongation of lipolysis, particularly during the first few weeks after parturition. The increased lipolysis after parturition leads to a major increase in the hepatic triacylglycerol concentration and to a shift in hepatic fatty acid composition. Unrestricted feed intake during the dry period impairs postpartum oxidation and synthesis of fatty acids in the liver of dairy cows.

In Australia, only beef cattle have been involved in pregnancy toxemia; the fat and the obese are most commonly affected. The disease occurred most notably when there was a shift to autumn calving (February to April) when feed supplies were low because of low late-summer rainfall. The cows were in good to fat body condition because of lush pastures in the spring and early summer, but by autumn when the calving season approached, the feed supplies were low and the nutritive value of the pasture inadequate. The lack of feed combined with the expensive nature of supplementary feeding resulted in an inadequate level of nutrition during late pregnancy. The morbidity is usually from 1% to 3%, but may be as high as 10%, and the disease is usually fatal.

PATHOGENESIS

Fatty liver is associated with a negative energy balance that is essentially universal in dairy cows in the first few weeks of lactation. Most cows adapt to the negative energy balance through an intricate mechanism of metabolic adaptation. Fatty liver develops because of failure of these adaptive mechanisms. Under normal physiologic conditions, the total amount of fat increases in the liver beginning a few weeks before calving, rises to an average of about 20% (of wet-weight basis) 1 week after calving, and declines slowly to the normal level of less than 5% by 26 weeks after calving. However, the fat content varies from almost none to 70% among cows 1 week after calving. Fat mobilization begins about 2 to 3 weeks before calving and is probably induced by a changing hormonal environment before calving rather than an energy deficit. After calving, there is a larger increase in fat accumulation. The changes in the liver in dairy cows are functional and reversible and related to the metabolic demands of late pregnancy and early lactation.

The heavy demands for energy in the high-producing dairy cow immediately after parturition, or in the pregnant beef cow that may be bearing twins, result in an increased rate of mobilization of fat from body reserves, usually subcutaneous fat, to the blood that transports it to body tissues, particularly the liver but also muscle and the kidneys. Any decrease in energy intake caused by a shortage of feed or an inability of the cow to consume an adequate amount of feed during the critical periods of late pregnancy or early lactation results in the mobilization of an excessive amount of nonesterified fatty acids (NEFAs). This results in increased hepatic lipogenesis with accumulation of lipid in enlarged hepatocytes, depletion of liver glycogen, and inadequate transport of lipoprotein from the liver. Most of the lipid infiltration of the liver in dairy cows after calving is in the form of triacylglycerols because of the increased uptake of NEFAs and a simultaneous increase in diacylglycerol acyltransferase; the activity of this enzyme is activated by fatty acids. The gradual increase in plasma NEFA concentration during the first prepartum days may explain the gradual depression in dry matter intake and a contributing factor to triglyceride accumulation in the liver. During this period there is also an elevated concentration of plasma glucose and a lowered plasma BHBA concentration. The serum lecithin:cholesterol acyltransferase activity in spontaneous cases of fatty liver in cows is also decreased, which may be associated with reproductive performance because cholesteryl esters are utilized for the synthesis of steroid hormones.

Cattle are prone to fatty liver because their hepatocytes have limited capacity to export VLDLs and therefore a limited ability to export accumulated fat in the hepatocytes. NEFAs transported to the liver are usually oxidized in the mitochondria and peroxisomes or secreted as VLDL particles into the blood. Fatty liver develops when the
uptake of NEFAs by the liver exceeds the oxidation of NEFAs by the liver to CO₂, partial oxidation of NEFAs to form ketones, and export of phospholipids, cholesterol, and apoproteins from the liver as lipoproteins. For unknown reasons, the capacity for VLDL formation is low in cattle and further impaired in early-lactating cows as a result of very low apolipoprotein B100 (apoB100) availability, the main apolipoprotein of VLDL particles. Production of ketones in moderate levels is beneficial in that energy is exported from the liver to other tissues that can utilize ketones as an energy source. Excess lipids that cannot be exported are stored as triacylglycerol in the liver and are associated with decreased metabolic functions of the liver. Also, a prepartum surge of estrogen may contribute to the development of fatty liver in ruminants by increased fatty acid esterification along with limited export of triglyceride.

During fat mobilization, there is a concurrent loss of body condition and adipose tissue. The degree of mobilization will be dependent on the fatness of the cow and the extent of the energy deficit. Fat and thin cows respond differently to the metabolic demands of early lactation. Fat cows appear less able to utilize mobilized fatty acids, and as a result they accumulate esterified fat in tissues. This can adversely influence susceptibility to disease, and the response of the cow to that disease imposes further metabolic demands, particularly on muscle and protein metabolism. Both fat and skeletal muscle mass are decreased after calving, and fat cows lose 2.5 times more muscle fiber area than thin cows. Thus the loss of body condition is a result of total tissue mobilization (protein and fat) rather than fat alone. There appears to be a higher rate of protein mobilization in fat cows than in thin cows.

Cows that are not fat initially do not develop fatty liver syndrome. Pregnant beef cows in thin body condition on pasture can become extremely emaciated and eventually recumbent and die of starvation, but they do not develop pregnancy toxemia.

**CLINICAL FINDINGS**

In dairy cattle, fat-cow syndrome occurs usually within the first few days following parturition and is commonly precipitated by any condition that interferes with the animal's appetite temporarily, such as the following:

- Parturient hypocalcemia
- Left-sided displacement of the abomasum
- Indigestion
- Retained fetal membranes
- Dystocia

Affected cows are usually excessively fat, with a BCS of 4/5 or higher. Excessive quantities of subcutaneous fat are palpable over the flanks, the shoulder areas, and around the tailhead. The affected cow usually does not respond to treatment for some of these diseases and becomes anorexic. The temperature, heart rate, and respiration are within normal ranges. Rumen contractions are weak or absent, and the feces are usually scant. Periods of prolonged recumbency are common, and affected cows may have difficulty in standing when they are coaxed to stand. A severe ketosis that does not respond to the usual treatment may occur. There is marked ketonuria. Affected cows will not eat and gradually become weaker and progress to totally recumbent, and they die in 7 to 10 days. Some cattle exhibit nervous signs consisting of a staring gaze, holding the head high, and muscular tremors of the head and neck. Some severe cases appear to develop hepatic failure, do not respond to therapy, and become weak and recumbent and die. Terminally there is coma, tachycardia, and marked hyperglycemia. The case-fatality rate in severe cases may reach 50% or more.

In fat beef cattle shortly before calving, affected cows are aggressive, restless, excited, and uncoordinated with a stumbling gait; sometimes have difficulty in rising; and they fall easily. The feces are scant and firm, and there is tachycardia. When the disease occurs 2 months before calving, the cows are depressed for 10 to 14 days and do not eat. Eventually they become stonily recumbent. The respirations are rapid, there may be an expiratory grunt, and the nasal discharge is clear, but there may be flaking of the epithelium of the muzzle. The feces are usually scant; terminally, there is often a fetid yellow diarrhea. The disease is highly fatal; the course is 10 to 14 days, and terminally there may be coma, with cows dying quietly.

In dairy cattle with moderately severe fatty liver, the clinical findings are much less severe, and most will recover within several days if they continue to eat even small amounts of hay. In dairy cattle, there is a relationship between the occurrence of a subclinical fatty liver within the first few weeks after parturition and inferior reproductive performance as a result of a delay in the onset of normal estrus cycles and a reduction in the conception rate that results in an increase in the average days between calving and conception. There may be differences in reproductive performance between cows with mild and moderate fatty livers early after calving. However, an examination of the postpartum hormone profiles of cows with fatty liver did not reveal the pathogenic mechanism of the reduced fertility. Fat-cow syndrome may also be associated with an increased incidence of parturient paresis and unresponsive treatment for ketosis in early lactation.

**CLINICAL PATHOLOGY**

**Serum Biochemistry**

The biochemical changes associated with fatty liver syndrome in cows depend on the severity of the fatty liver. There is a significant association between increasing serum biochemical abnormalities with increasing amounts of liver fat, although there may be considerable overlap in the distribution of individual test values in a population of animals with suspected fatty liver.

Increased plasma/serum nonesterified fatty acid, acetoacetate, BHB, and total bilirubin concentrations, and decreased serum fructosamine concentration, are associated with increased liver fat percentage. Likewise, increased plasma/serum hepatic enzyme activity (particularly aspartate aminotransferase and ornithine carbamoyl transferase activity) is also associated with increased liver fat percentage. Other hepatic enzyme activities in plasma, such as alanine aminotransferase, sorbitol dehydrogenase, glutamate dehydrogenase, alkaline phosphatase, and gamma-glutamyl transferase activities, are poorly associated with liver fat percentage. Possibly the most relevant biochemical index of the liver fat percentage is the plasma NEFA:cholesterol ratio. The rationale for using this ratio is that the plasma NEFA concentration reflects a metabolite that has not been cleared by the liver, whereas the plasma cholesterol concentration reflects the rate of hepatic reesterification and export as a VLDL. A high plasma NEFA:cholesterol concentration therefore is thought to indicate a high liver fat percentage. An increased concentration of plasma total bilirubin is also associated with increased liver fat percentage; competition between bilirubin and NEFA for the same binding site on hepatocytes decreases the hepatic uptake of bilirubin and therefore results in hyperbilirubinemia. Serum fructosamine concentration provides a retrospective record of serum/plasma glucose concentrations over the previous 1 to 3 weeks and therefore provides a useful longer-term index of glucose availability. Serum fructosamine concentrations less than 213 µmol/L are predictive of hepatic lipodosis in dairy cattle.

The plasma ammonia concentration in arterial or venous samples is poorly associated with liver fat percentage, but it is an excellent indicator of hepatic failure in severely affected cattle with hepatic lipodosis. In cattle, ammonia in plasma is derived mainly from bacterial activity in the rumen and metabolism of tissue amino acids and is converted to urea by the liver or glutamine by the liver and other tissues. Consequently, severe liver dysfunction results in elevated plasma ammonia concentrations (>29 µmol/L), with higher ammonia concentrations in arterial samples than venous samples because of nonhepatic metabolism of ammonia.

Several cow-side blood, urine, and milk ketone tests are available for the detection of subclinical ketosis in postpartum dairy cows (see previous section on ketosis and subclinical ketosis). Metabolomic biomarkers show promise in identifying a typically pattern
of changes in cattle with hepatic lipidosis; for example, plasma fibrinogen decreases inversely with the severity of hepatic lipido- 
sis, presumably because of intracellular lipid accumulation interferes with fibrinogen synthesis.

**Hemogram**

In cattle with subclinical fatty liver, there may be a leukopenia, neutropenia, and lymphopenia. Leukopenia has been observed in dairy cows with more than 20% liver fat in the second week after calving. This may be related to the increased incidence of postpartum diseases, such as mastitis and endo-
metritis, observed in cows with subclinical fatty liver. In cows with fatty liver, there is decreased functional capacity of the poly-
morphonuclear cells. However, this is not necessarily a cause-and-effect relationship.

**Liver Biopsy and Analysis**

The severity of fatty liver has been arbitrarily classified into severe, moderate, and mild, based on the amount of triglyceride present in the hepatocytes. In severe hepatic lipidosis, the accumulation of triglyceride in the cytoplasm is accompanied by disturbances in hepatic structure and function that may result in hypoglycemia and ketonemia; these signs are manifested as anorexia and depression, and there may be clinical evidence of nervous signs. A liver biopsy can be used to determine the severity of the fatty liver and the concentration of triglyceride and is the most reliable method of accurately estimating the degree of fatty infiltration of the liver.

The triglyceride concentration of liver in normal cows ranges from 10% to 15% on a wet-weight basis. Estimation of the lipid content of bovine liver samples obtained by biopsy may be made by biochemical or histologic methods. Both methods provide reasonable estimates of liver fat content over a wide range of values. The lipid content of bovine liver is highly correlated with its specific gravity and the submersion of needle biopsy specimens into water, and copper sulfate solutions with specific gravities of 1.025 and 1.055 can be used as a test to estimate lipid content. For routine clinical diagnosis, three solutions of specific gravities of 1, 1.025, and 1.055 can be used. Liver samples that float in all three solutions contain more than 34% lipid, those that sink in water but float in solutions of 1.025 and 1.055 specific gravity contain less than 34% but greater than 25% lipid, whereas those that float only in solutions of 1.055 specific gravity contain less than 25% but greater than 13% lipid. Samples that sink in all three solutions contain less than 13% lipid. Some limited evidence indicates that cows with liver lipid concentrations above 34% are severely affected and can be expected to have clinical manifestations of hepatic insufficiency. Those with liver lipid levels between 34% and 25% are moderately affected and might have some clinical evidence of hepatic insufficiency. Those between 25% and 13% are mildly affected, which is the range of most postpartum dairy cows without any evidence of disease. Liver lipid concentrations below 13% are inconsequential.

**Ultrasoundography of the Liver**

Ultrasoundography of the liver has been used to evaluate fatty infiltration in dairy cattle with mixed results. Two strategies have been employed: identification of hepatic enlargement by comparing liver position with published reference range relative to the ribs, and the echogenicity or brightness of the liver. In the normal cow, the hepatic ultra-
sonogram consists of numerous weak echoes distributed homogeneously over the entire area of the liver. The echo beam gradually attenuates as it passes through the normal liver tissue. The portal and hepatic veins can be seen within the normal echotexture, and the parenchymal edges are normally visible. In the fatty liver, there is a diffuse nature and echogenicity that are roughly proportional to the volume of fat vacuoles and the amount of triglyceride in the liver. Assessment of echogenicity is subjective and varies with equipment and settings on the ultrasono-
graphic unit. Consequently, objective ultra-
sonographic indices of hepatic lipidosis are under investigation, such as spectral analysis and analysis of brightness (B)-mode image statistics and texture characteristics. Technological challenges associated with digital processing of ultrasonographic images of the liver need to be resolved before the noninva-
sive measurement of liver fat percentage becomes a widely available diagnostic tool.

**Necropsy Findings**

In severe fatal cases, the liver is grossly enlarged, pale yellow, friable, and greasy. Mild and moderate cases are usually not fatal unless accompanied by another fatal disease, such as peracute mastitis. The degree of fatty infiltration in these instances is much less obvious. The histologic changes include the occurrence of fatty cysts or lipogranulomas, enlarged hepatocytes, compression of hepatic sinusoids, a decreased volume of rough endo-

cyttoplasmic reticulum, and evidence of mito-

chondrial damage. The latter two changes are reflected in reduced albumin levels and increased activities of liver enzymes in the blood. The proportions of the various fatty acids in the liver are altered considerably. Pal-
mic and oleic acid proportions are higher in fatty-liver cows than in normal cows, whereas stearic acid is lower.

**Differential Diagnosis**

In dairy cows, fatty liver must be differentiated from those diseases that occur commonly immediately following parturition. Left-sided displacement of the abomasum results in a secondary ketosis, inappetence, and pings over the left abdomen.

**Retained Placenta and metritis** may be accompanied by fever, inappetence to anorexia, ruminal atony, and a foul-smelling vaginal discharge. A degree of fatty liver may occur in these cows, making it indistinguishable from the effects of the retained placenta and metritis.

**Primary ketosis** may occur immediately after parturition or within several days rather than at the most common time, at 6 to 8 weeks of lactation. Inappetence, ruminal hypo-
tonicity, marked ketonuria, and a good response to glucose and propylene glycol are characteristic.

**In beef cattle, pregnancy toxemia** before parturition must be differentiated from abdominal impaction, vagus indigestion, and chronic peritonitis.

**TREATMENT**

The prognosis for severe fatty liver is unfa-
vorable. In general, cows with the severe fat-cow syndrome that are totally anorexic for 3 days or more usually die in spite of intensive therapy. The prognosis for cases with nervous signs is very poor. Liberal quantities of highly palatable good-quality hay and an ample supply of water should be provided. Cattle that continue to eat in increasing daily amounts will recover with supportive therapy and palatable feeds. The major prognostic factor is whether the cow will eat; failure of the appetite to return is usually a very poor prognostic sign.

Three treatment strategies for fatty liver are available. The most effective strategy is to decrease the rate of fat mobilization and therefore the plasma NEFA concentration; propylene glycol appears to act partly by this mechanism. The second strategy is to facilitate the complete oxidation of NEFAs in the liver. The third strategy is to increase the rate of export of VLDLs from the liver; choline is thought to act by this method. Because they address different mechanisms, combined treatment using propylene glycol and rumen-protected choline offers theoreti-
cal advantages. Several different therapeutic approaches have been tried and are discussed in detail in the previous section on ketosis and subclinical ketosis.

Additional treatments that have been tried in cattle with fatty liver include intrave-
rous fluids, ruminal transfaunaation, and glucagon.

**Fluid and Electrolyte Therapy.** Intensive therapy directed at correcting the effects of the ketosis and the fatty liver is required. The recommended treatment includes continu-
ous IV infusion of 5% glucose and multiple electrolyte solutions and the intraruminal administration of rumen juice (5 to 10 L) from normal cows in an attempt to stimulate
the appetite of affected cows. Water and multiple electrolytes (10 to 30 L) can be administered intraruminally.

**Glucagon.** The subcutaneous injection of 15 mg/d of glucagon for 14 days beginning at day 8 postpartum decreases liver triglyceride concentrations in cows older than 3.5 years. Glucagon, containing 29 amino acids, is a pancreatic hormone that improves the carbohydrate status of cows by stimulating hepatic gluconeogenesis, glycogenolysis, amino acid uptake, and ureagenesis. The effect of glucagon on lipid metabolism is both direct and indirect because it directly increases lipolysis in adipose tissue but indirectly decreases lipolysis by increasing concentrations of plasma glucose and insulin. IV infusions of glucagon are not practical for on-farm use.

**Glucocorticoids.** Dexamethasone-21-isonicotinate (20 to 25 mg, IM) decreases hepatic total lipid and triglyceride content in cattle after surgical correction of left-displaced abomasum, which is a beneficial effect.

**Propylene glycol** given orally at 300 mL/day for 5 days promotes gluconeogenesis and is used for the treatment of ketosis.

**Insulin** as zinc protamine at 200 to 300 SC twice daily promotes the peripheral utilization of glucose, but clinical results have been mixed. It is important to recognize that IV administration of insulin is always accompanied by insulin release, no matter the metabolic state of the cow. Consequently, IV glucose administration should be considered as a combined treatment with glucose and insulin.

**Outbreaks in a Herd.** When outbreaks of fat-cow syndrome occur in pregnant beef cattle, all remaining cows should be sorted into groups according to body condition and fed accordingly. Excessively fat cows should be fed the best-quality hay that is available along with a supplement. Fat cows should be exercised by feeding them on the ground and forcing them to walk.

**Metabolic Adaptations During the Transition Period**

The primary goal of nutritional management strategies of dairy cows during the transition period should be to support the metabolic adaptations that occur. The hallmark of the transition period of dairy cattle is the dramatic change in nutrient demands that necessitates exquisite coordination of metabolism to meet requirements for energy, amino acids, and calcium by the mammary gland after calving. Estimates of the demand for glucose, amino acids, fatty acids, and net energy by the gravid uterus at 250 days of gestation and the lactating mammary gland at 4 days postpartum indicate approximately a tripling of demand for glucose, a doubling of demand for amino acids, and approximately a fivefold increase in demand for fatty acids during this period. In addition, the requirement for calcium increases approximately fourfold on the day of parturition. The literature on the integration of metabolism and intake regulation in periparturient animals has been reviewed.

**Glucose Metabolism**

The primary homeorhetic adaptation of glucose metabolism to lactation is the concurrent increase in hepatic gluconeogenesis and decrease in oxidation of glucose by peripheral tissues to direct glucose to the mammary gland for lactose synthesis. The major substrates for hepatic gluconeogenesis are propionate from ruminal fermentation, lactate from Cori cycling, amino acids from protein catabolism or net portal-drained visceral absorption, and glycerol released during lipolysis in adipose tissue.

**Lipid Metabolism**

The primary homeorhetic adaptation of lipid metabolism to lactation is the mobilization of body fat stores to meet the overall energetic requirements of the cow during a period of negative energy balance in early lactation. Body fat is mobilized into the bloodstream in the form of NEFAs that are used to make upward of 40% of milk fat during the first days of lactation. Skeletal muscle uses some NEFA for fuel, particularly as it decreases its reliance on glucose as a fuel during early lactation. Given that NEFA concentrations increase in response to increased energy needs accompanied by inadequate feed intake, and plasma NEFA concentrations usually are inversely related. The liver takes up NEFAs in proportion to their supply, but the liver typically does not have sufficient capacity to completely dispose of NEFAs through export into blood or catabolism for energy. Therefore cows are predisposed to accumulate NEFAs as triglycerides within liver when large amounts of NEFA are released from adipose tissue into the circulation.

**Dry Matter Intake and Energy Balance in the Transition Period**

The literature on dry matter intake and energy balance in the transition period of the dairy cow has been reviewed.

The transition from late gestation to early lactation in the dairy cow is a critical period in the lactation–gestation cycle. During this period, feed intake is at the lowest level in the production cycle. In addition to the drop in feed intake, there is a concurrent transition from late gestation to lactation, with huge increases in energy demands. This leads to a negative energy balance that can result in ketosis or fatty liver. Voluntary dry matter intake (DMI) may decrease 25% and 52% during the final 14 days of gestation for first- and second-parity animals and aged (third and fourth or greater) cows, respectively. A negative energy balance can occur before parturition and is more likely to occur in heifers than cows because heifers have a lower DMI and an additional need for energy requirement for growth. The fall in DMI is the usual cause of a negative energy balance rather than an increase in energy requirements for fetal growth.

**Nutritional Management to Support Metabolic Adaptations During the Transition Period**

**Grouping Strategies**

The primary goal of nutritional management strategies of dairy cows during the transition period should be to support the metabolic adaptations just described. Industry-standard nutritional management of dairy cows during the dry period consists of a two-group nutritional scheme. The National
Research Council (NRC) Nutrient Requirements of Dairy Cattle recommends that a diet containing approximately 1.25 Mcal/kg of NE\textsubscript{L} should be fed from dry-off until approximately 21 days before calving, and that a diet containing 1.54 to 1.62 Mcal/kg of NE\textsubscript{L} should be fed during the last 3 weeks before calving. The primary rationale for feeding a lower-energy diet during the early part of the dry period is to minimize BCS gain during the dry period. During the last 3 to 4 weeks prepartum, a diet higher in energy and protein concentration than current NRC recommendations should be fed so that adequate nutrient intake occurs within the limits of the reduced voluntary dry matter intake. Supplying excessive energy to dairy cows during the early dry period may have detrimental carryover effects during the subsequent early lactation. Managing cows to achieve a BCS of approximately 3.0 at drying off rather than the traditional 3.5 is now recommended.

**Strategies to Meet Glucose Demands and Decrease NEFA Supply During the Transition Period**

**Carbohydrate Formulation of the Preparation Diet.** Feeding diets containing higher proportions of nonfiber carbohydrate (NCF) promotes ruminal microbial adaptation to NCF levels typical of diets fed during lactation and provides increased amounts of propionate to support hepatic gluconeogenesis and microbial protein (providing the diet contains sufficient ruminally degradable protein) to support protein requirements for maintenance, pregnancy, and mammaryogenesis.

**Direct Supplementation With Glucogenic Precursors.** Propylene glycol is a glucogenic precursor that has been used as an oral drench in the treatment of ketosis. Decreased concentrations of plasma NEFA and BHB follow oral administration of propylene glycol. The administration of an oral drench of propylene glycol for 2 days beginning at calving decreased concentrations of NEFA in plasma and increased milk yield during early lactation. However, in general, the lack of consistent production responses does not support a recommendation for routine use. Propionate supplements added to the diet to supply substrate for hepatic gluconeogenesis have also been used, but with inconsistent results. Glycerol given orally is an effective treatment for lactational ketosis in dairy cattle. Feeding glycerol to dairy cows from 14 days prepartum to 21 days in milk did not have the glucogenic effect attributed to it when given orally as a drench to individual cows.

Monensin provided in controlled-release capsules (CRCs) administered 2 to 4 weeks prepartum has been shown to decrease the incidence of energy-associated diseases, subclinical ketosis, and left-side displaced abomasum by 40%, and a 25% reduction in retained placenta was found. The capsule delivers 335 mg/d of monensin for 95 days. The common mechanism for reduction of the incidences of these energy-associated diseases is likely to be improved energy metabolism during the transition period. The net effect of monensin within the rumen is to increase ruminal propionate production at the expense of ruminal acetate and methane production so that propionate supply is increased and the overall energetic efficiency of ruminal fermentation is increased.

**Added Fat in Transition Diets.** It has been proposed that dietary fat may partially decrease concentrations of NEFA and prevent the occurrence of ketosis. Dietary long-chain fatty acids are absorbed into the lymphatic system and do not pass first through the liver. The fat can provide energy for peripheral tissues and the mammary gland, and the increased energy availability would in turn decrease mobilization of body fat and decrease plasma NEFA concentrations. However, available evidence indicates that added fat fed to cows during the prepartum period does not decrease plasma NEFA concentrations.

**Effects of Specific Fatty Acids on NEFA Supply.** A substantial amount of research has examined the metabolic roles of individual fatty acids in transition-cow nutrition and metabolism. Feeding trans-10, cis-12 conjugated linoleic acid or transstearidenoic acid experimentally may decrease the negative energy balance, but the ultimate metabolic effects in transition cows are as yet uncertain.

Because of the large economic losses associated with pregnancy toxemia in cattle, every economic effort must be made to prevent the disease. The principal method of control is to prevent pregnant cattle from becoming fat during the last trimester of pregnancy, particularly during the dry period in dairy cattle. During pregnancy, mature cattle should receive sufficient feed to meet the needs for maintenance and pregnancy, and the total daily nutrient intake must increase throughout the last trimester to meet the needs of the fetus. However, this increase is usually difficult to control without some cows getting fat and others losing weight. Sorting cows into groups on the basis of size and condition and feeding according is recommended. Metabolic profiles may be used as a means of assessing energy status and, correspondingly, the likelihood of occurrence hyperketonemia or pregnancy toxemia. Both plasma glucose and BHB concentrations can be used.

**Body-condition scoring of dairy cows** at strategic times can be used to monitor the nutritional status of the herd and minimize the incidence and severity of fatty liver syndrome. The scoring should be done throughout the production cycle as part of a herd health program. Scoring done at calving, at 21 to 40 days, and 90 to 110 days postpartum can be used to monitor the nutritional status of the herd. Scoring done at 100 to 60 days before drying off provides an opportunity for management to make appropriate adjustments in the feeding program so that optimal body-condition goals are achieved. The optimum BCS of a cow at calving that will result in the most economical amount of milk has not yet been determined. On a scale of 5, the suggested optimum score at calving has ranged from 3 to 4. The optimum score will probably depend on the characteristics of the individual herd, which include type of cow, type of feedstuffs available, season of the year, environmental temperature, and the people doing the actual body-condition scoring.

**REFERENCES**

**PREGNANCY TOXEMIA (TWIN LAMB DISEASE) IN SHEEP**

**SYNOPSIS**

**Etiology** A multifactorial disorder of energy metabolism, with hypoglycemia and ketonemia (the accumulation in blood of acetooacetate, β-hydroxybutyrate, and their decarboxylation products acetone and isopropanol).

**Epidemiology** The disease in sheep is associated with a falling plane of nutrition, principally in the last month of pregnancy in ewes bearing twins and triplets, but can be induced by other stress at this time.

**Clinical findings** Encephalopathy with blindness, muscle tremor, convulsions, metabolic acidosis, and a clinical course of 2 to 8 days, usually terminating fatally unless treated early.

**REFERENCES**

Clinical pathology  Hypoglycemia, ketonemia, ketonuria.
Necropsy findings  None specific. Twin lambs and fatty liver.
Diagnostic confirmation  Ketonemia, ketonuria, or elevated ketones in milk.
Elevated β-hydroxybutyrate (BHB) in aqueous humor of dead sheep.
Treatment  Parenteral glucose with corticosteroid and oral glucose precursors such as propylene glycol, occasionally insulin, or oral glucose and electrolyte therapy. Cesarean section or induction of parturition. Case fatality high.
Control  Monitoring of condition score, pasture availability, feeding, and biochemical indicators of ketosis. Correction of energy imbalance if detected.

ETIOLOGY
Hypoglycemia and hyperketonemia are the primary metabolic disturbances in pregnancy toxemia. The precipitating cause is the energy demand of the conceptus in the latter part of pregnancy. However, there is a great deal of variation between sheep flocks in the prevalence of the naturally occurring disease under conditions that appear conducive to its development. The most important factor in pregnancy toxemia is a decline in the plane of nutrition during the last 4 to 6 weeks of pregnancy. This is the period when fetal growth is rapid and the demands for energy are markedly increased, particularly in ewes carrying twins or triplets. For example, the energy requirement for a 70-kg ewe carrying twins increases 36% in the last weeks of pregnancy, from 13.5 MJ (3.2 Mcal)/d midgestation to 18.3 MJ (4.4 Mcal)/d at term. The disease in goats during late pregnancy has the same initiating causes.

Pregnancy toxemia can be classified according to the underlying management cause that is critical to its control and prevention:
- Primary pregnancy toxemia
- Fat-ewe pregnancy toxemia
- Starvation pregnancy toxemia
- Secondary pregnancy toxemia
- Stress-induced pregnancy toxemia

EPIDEMIOLOGY
Primary Pregnancy Toxemia
Primary pregnancy toxemia is the most common. In most flocks, it is a result of a declining plane of nutrition in the latter half of pregnancy, often exacerbated by a short period of food deprivation associated with a management procedure in late pregnancy, such as crutching, shearing, a change of environment, or drenching. In sheep grazing pastures the decreased plane of nutrition is often associated with inadequate pasture availability and/or overstocking. In sheep at pasture it occurs more frequently in early-lambing flocks, where there is insufficient supplement provided during autumn or winter. In some outbreaks, ewes have been moved onto better pasture during late pregnancy specifically to prevent the occurrence of ketosis, but if ewes are unaccustomed to the new feed, their intake of metabolizable energy will be reduced.

For sheep that are housed in late pregnancy, the provision of poor-quality hay may predispose pregnancy toxemia. A change in feed type, feeding of moldy feed, or feed contaminated with manure can also lead to decreased intake, especially with goats. Competition for inadequate trough space can also be important. Goats exhibit greater dominant/submissive behavior than sheep, and this can result in lower food intake in submissive goats in groups that are being fed a partial supplemental or total ration.

In all management systems, failing to identify and separate ewes bearing twins and triplets, and to feed them accordingly, or failing to increase the nutritional plane of mixed mobs of pregnant sheep during the last 6 weeks of pregnancy are important predisposing factors.

Fat-Ewe Pregnancy Toxemia
Fat-ewe pregnancy toxemia occurs without a specific stressor in ewes that are very well fed and are in an overfat condition in late pregnancy (a condition score of 4 or 5 on a scale of 1 [emaciated] to 5 [fat]). Fat ewes have a decreased food intake in late pregnancy when the volume of the rumen is reduced by the pressure of intraabdominal fat and the developing fetus. This can occur especially when feeds with high water content are being fed, such as silage or root crops. A lack of exercise is thought to predispose this type of pregnancy toxemia, and there is often concurrent hypocalcemia.

Starvation Pregnancy Toxemia
Starvation pregnancy toxemia occurs in ewes that are excessively thin. It is relatively uncommon, but it occurs in extensive grazing systems where there is prolonged drought and an inadequate alternative feed supply. It can occur in any production system where there is mismanagement and undernutrition.

Secondary Pregnancy Toxemia
Secondary pregnancy toxemia usually occurs as a sporadic disease as the result of the effect of an intermittent disease, such as foot rot or foot abscess, that affects food intake. Heavy worm infestation, such as mixed infections of Teladorsagia, Haemonchus, or Trichostrongylus species, would add a similar drain on glucose metabolism and increase the chances of development of this condition.

Stress-Induced Pregnancy Toxemia
Stress-induced pregnancy toxemia is the least common variant of this condition, in which stress is the initiator. Examples are the close shepherding or housing of late-pregnant sheep of breeds not used to being housed, the transport of late pregnant sheep, and outbreaks following attack by dogs.

Occurrence
Pregnancy toxemia is seen primarily in ewes carrying triplet or twin lambs in the last 6 weeks of pregnancy, with the peak incidence in the last 2 weeks of pregnancy. It occurs wherever sheep are raised, but it is primarily a disease of sheep raised in intensive farming systems, either grazing or when housed during the winter. In part this is because the breeds of sheep used in intensive farming are more likely to bear twins or triplets. In contrast, sheep breeds in extensive grazing systems commonly bear single lambs, and significant outbreaks of pregnancy toxemia are uncommon except where there is drought or insufficient pasture as a result of poor management. The attack rate in a flock varies with the nature and severity of the nutritional deprivation and the proportion of the flock at risk. It can be very high in starvation pregnancy toxemia, whereas fat-ewe pregnancy toxemia is generally sporadic. In outbreaks that follow management procedures or other stressors, clinical disease is not seen until 48 hours afterward, and new cases will develop over several days. Intercurrent disease in late-pregnant ewes, such as foot rot or foot abscess, may predispose pregnancy toxemia.

The natural incidence in intensively farmed sheep is approximately 2% of pregnant ewes, but where there are severe management deficiencies it may affect the majority of late-pregnant ewes. The proportion of flocks with cases varies by year, but in a study of sheep diseases in Canada, 19% of flocks reported cases of pregnancy toxemia. The case fatality is high unless treatment is initiated early in the clinical course, but even with early treatment many ewes will die.

Experimental Reproduction
Hypoglycemia and ketosis can be experimentally produced in pregnant sheep by undernourishment, but the resultant syndrome has biochemical and clinical differences from spontaneously occurring pregnancy toxemia. For example, loss of appetite is an early sign in the spontaneous disease, whereas starved experimental animals, even though hypoglycemic and ketotic, will eat feed when offered. Consequently, there is debate about whether hypoglycemia is the primary precipitating cause of the clinical signs in the naturally occurring disease.

There is a great deal of variation between sheep in the ease with which the hypoglycemia and ketosis can be produced experimentally and in the variation in incidence of the naturally occurring disease in conditions that appear to be conducive to it developing. It is likely that the difference between sheep
depends on the metabolic efficiency of the liver.

**Animal Risk Factors**

**Pregnancy**
The disease occurs only in ewes in the last 6 weeks of pregnancy, with the peak incidence in the last 2 weeks. It occurs primarily in ewes carrying triplet or twin lambs, although ewes bearing a single, large lamb may also be affected.

**Parity**
The disease is uncommon in maiden ewes because of their lower fecundity, and then increases in prevalence up until 5 to 6 years of age.

**Breed**
Breed differences largely reflect differences in fecundity and differences in management systems. Thus the disease is more common in British lowland breeds and their crosses than the Merino. British hill-breeds are traditionally thought to be more resistant to the development of pregnancy toxemia in the face of nutritional deprivation of the ewe, but resistance is achieved at the expense of lamb birth weight and has the penalty of higher neonatal mortality. Differences in the susceptibility of individual sheep appear to be related to differences in rates of hepatic gluconeogenesis.

**Economic Significance**
The disease has considerable effect. Without treatment, the case-fatality rate can approach 100%, and in individual flocks the prevalence can be high enough to be classed as an outbreak. Treated ewes that recover may have dystocia and die during parturition or develop retained placenta and metritis. Flocks that experience pregnancy toxemia also have a significantly higher-than-normal mortality in neonatal lambs and often a severe decrease in wool quality. Often these flocks are also predisposed to hypomagnesemia during lactation.

**PATHOGENESIS**
Approximately 60% of fetal growth takes place in the last 6 weeks of pregnancy, and pregnancy toxemia results from inadequate energy intake during this time, usually in ewes with more than one fetus. Ewes that are predisposed to the disease have an ineffective gluconeogenic response to the continued preferential demands for glucose by the growing fetuses, resulting in hypoglycemia, lipid mobilization, and the accumulation of ketone bodies and cortisol. The reason for this predisposition is not precisely known, but the subsequent disease and metabolic changes are associated with excessive lipid mobilization. Elevated concentrations of BHB further suppress endogenous glucose production and exaggerate the development of ketosis. Thus the negative feedback of hyperketonemia on glucose production produces a self-perpetuating cycle.

An encephalopathy develops, thought to be a hypoglycemic encephalopathy from hypoglycemia in the early stages of the disease. The encephalopathy and the disease are frequently not reversible unless treated in the early stages. The onset of clinical signs is always preceded by hypoglycemia and hyperketonemia, although it is not related to the minimum blood glucose or maximum ketone levels, and thus hypoglycemia may not be the initial or precipitating cause of the syndrome. In affected ewes, there is an abnormally high level of cortisol in plasma, and adrenal steroid diabetes (“insulin resistance”) may either contribute to or be a predisposing factor. For example, a comparison of ewes with a high risk of pregnancy toxemia (German Blackheaded Mutton) with a breed of lower risk (Finnish Landrace) found that the glucose elimination rate and glucose stimulated first-phase insulin secretion was lower and the basal rate of lipolysis significantly higher in the high-risk ewes. However, further investigation of insulin resistance and impaired insulin sensitivity, and the underlying cause of pregnancy toxemia, is needed.

The increase in plasma concentrations of nonesterified fatty acids depresses cellular and humoral immune responses in the experimentally produced disease, but the clinical significance of this to naturally occurring disease is not clear. Renal dysfunction is also apparent in the terminal stages of ovine ketosis and contributes to the development of clinical signs and the fatal outcome.

Those ewes that are carrying only one lamb and have been well fed before a short period of undernutrition may develop a subacute syndrome, both clinically and biochemically. In lines of ewe selected for increased fecundity, ewes bearing more than three fetuses have an increased susceptibility to pregnancy toxemia.

**CLINICAL FINDINGS**
The earliest signs of ovine ketosis are separation from the group, altered mental state, and apparent blindness, manifested by an alert bearing but a disinclination to move. Sheep at pasture may fail to come up for supplementary feeding, and housed sheep may stand near the feed trough with other sheep but not eat. The ewe will stand still when approached by attendants or dogs and will turn and face them, but it will make no attempt to escape. If it is forced to move, it blunders into objects; when an obstacle is encountered, it presses against it with its head. Many affected ewes stand in water troughs all day and lap the water. Constipation with dry, scanty feces is common, and there is grinding of the teeth.

In later stages, marked drowsiness develops, and episodes of more severe nervous signs occur, but they may be infrequent and easily missed. In these episodes, tremors of the muscles of the head cause twitching of the lips, champing of the jaws, and salivation, and these are accompanied by a cog-wheel type of clonic contraction of the cervical muscles causing dorsiflexion or lateral deviation of the head, followed by circling. The muscle tremor usually spreads to involve the whole body, and the ewe falls with tonic-clonic convulsions. The ewe lies quietly after each convulsion and rises normally afterward, but is still blind.

Between the convulsions there is marked drowsiness that may be accompanied by head pressing; assumption of abnormal postures, including unusual positions of the limbs and elevation of the chin (the “stargazing” posture); and incoordination and falling when attempting to walk. A smell of ketones may be detectable on the breath.

Affected ewes usually become recumbent in 3 to 4 days, although the clinical course is shorter in fat ewes. Terminally there may be a fetid diarrhea.

Fetal death often occurs and is followed by transient recovery of the ewe, but the toxemia caused by the decomposing fetus soon causes a relapse.

Affected ewes commonly have difficulty in lambing. Recovery may occur after the ewe lambs or if the lambs are removed by cesarean section in the early stages of the disease. In an affected flock, the disease usually takes the form of a slow, prolonged outbreak, with a few ewes affected each day over a period of several weeks. Recovered ewes may subsequently show a break in the wool.

**NECROPSY FINDINGS**
Without treatment, pregnancy toxemia in ewes is almost always fatal. At necropsy, there is severe fatty degeneration of the liver and usually constipation, although some
cases have fetid, light-colored diarrhea. A large single or, more commonly, twin or greater number of fetuses are present. These may have died before the ewe and be in varying stages of decomposition.

Histopathologically there is hepatic lipodosis and a poorly defined renal lesion, and there may be evidence of neuronal necrosis. Hepatic glycogen concentrations are usually very low. Concentrations of BHB in the aqueous humor or the CSF greater than 2.5 mmol/L or 5.0 mmol/L respectively, are supportive of a diagnosis of pregnancy toxemia.

**DIFFERENTIAL DIAGNOSIS**

Pregnancy toxemia is usually suspected in late-pregnant ewes that show nervous signs and die within 2 to 7 days. There may be a history of exertion, stress, or sudden deprivation of food. Hypocalcemia can occur under similar circumstances, but the following help in differentiation:

1. The onset is within 12 hours of the stress.
2. A considerable proportion of the flock will be affected at the same time.
3. There is obvious myasthenia.
4. It has a much shorter course, 12 to 24 hours.
5. Affected animals respond well to treatment with solutions of calcium salts.

**CONSIDERATIONS**

- **Listeriosis**
- **Cerebral abscess**
- **Acidosis**
- **Uterine torsion or impending abortion**
- **Rabies**

**TREATMENT**

Sheep treated very early in the course of the disease generally respond favorably, but response to therapy is poor once sheep have become recumbent, and the IV administration of 50% dextrose at this time may hasten death. Optimum therapy requires the correction of fluid, electrolyte, and acid-base disturbances in addition to treating with glucose.

**Parenteral Therapy**

Ideally, individual sheep should be examined biochemically and the corrective therapy based on these results, with fluids, electrolytes, and glucose (dextrose) given over a prolonged period. A recommendation for glucose therapy is the administration of 5 to 7 g of glucose IV 6 to 8 times a day in conjunction with 20 to 40 units of zinc protamine insulin given IM every other day for 3 days. However, in many sheep-raising areas intensive laboratory monitoring and such intensive therapy is not possible because of lack of access, expense, or the number of sheep involved in an outbreak. In the absence of biochemical monitoring, therapy with glucose should be accompanied by the IV injection of isotonic sodium bicarbonate or lactated Ringer’s solution, with additional fluids given by a stomach tube.

Standard doses of corticosteroids have little therapeutic effect in sheep, and thus treatment with these drugs is not recommended, although they are often used. Very large doses are effective in ewes still able to stand, but the success probably rests in the removal of the glucose drain by the induction of premature parturition.

**Oral Therapy**

Oral propylene glycol or glycerin (100 mL once daily) can be used to support parenteral glucosethylotherapy. Less intensive therapy with propylene glycol or glycerin alone can give excellent results, especially with early treatment, but is less successful with longer-standing cases. Oral drenching every 4 to 8 hours with 160 mL of a commercial calf scours concentrate (containing 28% glucose, 3.9% glycine, 5.3% sodium chloride, and other electrolytes) induces higher blood concentrations of glucose compared with drenching with glycerol or propylene glycol. Reported recovery rates are 90% in early and 55% in advanced cases. For the more intensive treatment of valuable ewes, insulin (0.4 IU/kg/d SC), combined with oral glucose precursors and electrolytes, may improve survival compared with treatment with oral glucose precursors and electrolytes alone.

Induction of parturition is an option, but it should only be used if the ewe is in the early stage of the disease because there is a delay in the delivery of the lambs (24 hours or more). If the ewe is unlikely to survive this period, cesarean section may be a better option. Induction can be achieved with dexamethasone 21-isonicotinate or the sodium phosphate form, at a dose rate of 16 to 25 mg per ewe, but dexamethasone tri-methylacetate appears to be ineffective. Lambs will be born 24 to 72 hours after injection, with most born within 36 hours. Induction of parturition in normal sheep can be achieved with 10 mg of betamethasone or 2.5 mg of flumethasone, but there are no reports of their efficacy in sheep with pregnancy toxemia.

**Cesarean Section**

Cesarean section can be used as an alternate to glucose replacement, and provided that ewes are in the early stages of the disease, removal of the lambs by cesarean section probably has the greatest success. The demand for glucose by the lambs is immediately removed, and both the ewe and the lambs have a high chance of survival, provided that the cesarean section is conducted before there is irreversible brain damage in the ewe and the lambs are close to term. If the ewe is recumbent, then chances of survival, for both the ewe and the lamb, are reduced. The lamb may already be dead, and thus ultrasound examination will inform fetal age and condition and hence whether to undertake a cesarean section.

</tbody>
</table>

**CONTROL**

When clinical cases occur, the rest of the flock should be examined daily for evidence of ketosis, and affected animals should be treated immediately with oral glucose/glycine/electrolyte or propylene glycol/glycerol. Supplementary feeding of the flock should immediately be increased or started, with particular attention given to increasing in the intake of energy (carbohydrate). However, care is needed with cereal grains because rapid introduction can cause ruminal acidosis, and ewes may need from 0.25 to 1 kg/ head per day (0.5 to 2.0 lb/head per day). Consequently, good-quality lucerne hay or legume grains, such as lupins or field peas, may be a safer option if ewes are not currently being fed a grain-based supplement, even though ewes do not need the higher protein content of these feeds.

**Prevention**

Ensure that the plane of nutrition is rising in the second half of pregnancy, even if it means restricting the diet in the early stages. An ideal condition score for ewes at 90 days of gestation is 2.75 to 3.0 on a scale of 1 to 5. If necessary, ewes with higher condition scores at the end of the first month of pregnancy can be fed to slowly lose 0.5 in condition score during the period to the third month of pregnancy without any detrimental effect on the ewe or the size or viability of the lamb. In many smaller flocks ewes tend to be in
excessively high condition score early in pregnancy. The last 2 months are important in the prevention of pregnancy toxemia because 70% of the lamb's birth weight is gained during the last 6 weeks of pregnancy. In intensively managed flocks the provision of cereal grain or a concentrate containing 10% protein during this period, at the rate of 0.25 kg/d, increasing to 1 kg/d in the last 2 weeks, provides adequate energy. During this period, there should be an increase in body weight of 10% for ewes with single lambs and 18% in those carrying twins, but the average condition score should remain around 3.0. Higher body-condition scores can result in higher birth weight of lambs, but this is usually not a financially viable strategy, and it increases the risk of fat-ewe pregnancy toxemia and dystocia. At the beginning of the fourth month of pregnancy, the flock can be divided into three groups by condition score, suboptimal, acceptable, and excess (overfat), and the groups are then fed accordingly. These can be monitored by condition scoring every 2 to 3 weeks during the fourth and fifth months of pregnancy. Maiden ewes should be fed as a separate group to provide for their growth in addition to pregnancy. Attention should also be given to broken-mouthed or older ewes to ensure that they maintain adequate body condition.

There are too many variations in flock structure and husbandry systems to discuss nutritional management in great detail here; readers should consult specialist texts appropriate to the system they work in. However, in more intensive systems, especially prime lamb production, ewes can be pregnancy tested by ultrasound and divided into groups depending on whether they are barren or are carrying single or multiple fetuses. Account needs to be taken of those ewes (and does) that are timid and are thus, or for other reasons, slow feeders. If there is insufficient trough space or if the supplement is fed in small amounts and highly edible, a proportion may get little or no feed. The cost-effectiveness of a feeding program should be evaluated. In breeds with low twinning rates and the groups are then fed accordingly.

Flock monitoring for latent pregnancy toxemia during the last 6 weeks of pregnancy can be conducted using serum BHB; concentrations of 0.8 mmol/L indicate adequate energy intake, 0.8 to 1.6 mmol/L indicate inadequate energy intake, and greater than 1.6 mmol/L indicate severe undernourishment. Pooled samples can reduce the cost of analysis, but serum glucose and BHB concentrations do vary significantly between flocks.

Ionophores are used in transition rations for dairy cows to prevent subclinical ketosis. There is some evidence that feeding monensin may have benefits for the energy metabolism of late pregnant ewes. Lower serum BHB, lowered feed intake, and improved feed efficiency have been observed, and thus further investigation of this strategy is warranted.

FURTHER READING

STEATITIS, PANNICULITIS, AND FAT NECROSIS

Steatitis is inflammation of adipose tissue and can affect any fatty tissue. Clinical expression is usually because of inflammation of intraabdominal or subcutaneous fat (panniculitis). The disease can be relatively innocuous or fulminant and is reported for cattle, in which it is referred to as fat necrosis or bovine lipomatosis, and horses. The colloquial name is “yellow-fat disease” because of the color of affected tissues—a result of accumulation of lipofuscin and products of fat oxidation. The disease is not neoplastic. The disease in cattle is characterized by inflammation and necrosis of fat in the abdominal cavity. It can be clinically silent with lesions detected during rectal examination for pregnancy diagnosis or other reason. Clinical signs of the disease in cattle are usually attributable to space-occupying lesions (such as compression of the rectum) or intestinal obstruction as a result of constriction of the intestine by mesenteric accumulation of fat or fibrotic constriction of the lumen. The lesions are firm masses present in any portion of the omental, mesenteric, or retroperitoneal fat or as mobile, free-floating structures in the abdomen. The free-floating masses do not appear to originate from necrosis of fat. The masses range from small nodules to large, solid, and irregularly shaped tumors. Unlike in horses, in which intraabdominal lipomas are often pedunculated (see Chapter 7) and cause acute intestinal obstruction when the peduncular stalk wraps and constricts the small intestine, the lesions in cattle are seldom pedunculated.

The clinical disease in cattle can be variable and range from silent through inappetence, decreased milk production, persistent diarrhea, mild recurrent colic, acute colic, dystocia, urinary retention of feces, and decreased passage of feces. Masses can be detected on rectal examination or laparotomy. Ultrasonography (transcutaneous or transrectal) can be useful in detecting and characterizing the lesions. The lesions are present as heterogeneous hyperechoic masses in the retroperitoneal, omental, or mesenteric fat. A hyperechoic ring around the kidney is common. Affected tissues can be biopsied with ultrasonographic guidance.

Abnormalities in the hemogram and serum biochemistry are confined to indicators of inflammation (neutrophilia), hypergammaglobulinemia, decreased concentrations of phospholipids and cholesterol, and an increase in concentration of free fatty acids.

The disease must be differentiated from lymphosarcoma, adenocarcinoma, intraabdominal abscess, or dry fecal balls in the descending colon. The lesions are composed of necrotic fat embedded in normal adipose tissue with mild inflammatory infiltrates of neutrophils, lymphocytes, plasma cells, macrophages and giant cells, and fibrosis. There is rarely evidence of pancreatitis in the disease in cattle.

The cause of the disease is unknown, although a prevalence of 67% is reported in steers grazing tall fescue, in which serum cholesterol concentrations were abnormally low.

The disease in horses affects mostly foals and young animals and ponies. Older animals are less frequently affected. Generalized steatitis can be a fulminant disease in horses, ponies, and foals. Panniculitis, an unusual form of steatitis limited to the subcutaneous tissues, has been reported in an aged pony mare and in perivaginal tissues after dystocia. Perivaginal steatitis included involvement of the bladder ligament and subsequent rupture of the bladder.

The clinical signs of generalized steatitis consist of anorexia and depression, fever, tachycardia, and subcutaneous edema. Painful subcutaneous swellings can occur in the nuchal crest and inguinal and axillary regions. Affected horses often have mild to moderate colic and signs of abdominal tenderness. Rectal examination reveals painful masses in the mesentery of some horses.

Hematology and serum biochemical examination reveal mild to moderate leukocytosis, with occasional horses having leukopenia, hypoproteinemia, hypoalbuminemia, and increases in activity in serum of lactate dehydrogenase (LDH), aspartate aminotransferase (AST), GGT, and lipase and amylase. Serum vitamin E concentrations are sometimes abnormally low. Biopsy of some of the SC swelling reveals histopathological evidence of fat necrosis with mineralization. At necropsy, the fat is hard, dry, and yellow-white, with areas of necrosis forming abscess-like lesions up to 3 cm deep and 10 cm in diameter. The fat lining the abdominal wall may contain firm yellow-white and red tissue nodules up to 3 cm in diameter. Pancreatitis is evident in equids with systemic disease, and there is necrosis and inflammation in most fatty...
tissues (subcutaneous, retroperitoneal, mesenteric, and omental). Generalized steatitis with fat necrosis (“yellow-fat disease”) has been recognized in many species at various ages and is thought to be related to a dietary deficiency of vitamin E and selenium and intake of unsaturated fatty acids.1,5

**DEFICIENCY OF UMP SYNTHASE (DUMPS)**

This is a partial deficiency of an enzyme that is involved in the conversion of orotate to uridine 5’-monophosphate (UMP) as a step in the synthesis of pyrimidine nucleotides. It is recorded at a high prevalence in Holstein–Friesian cattle in the United States and JapaneSE Black cattle and is characterized by an autosomal-recessive form of inheritance and the secretion of high levels of orotate in the milk.1 Heterozygous animals have a partial deficiency of UMP synthase, but they have no individual or herd clinical abnormalities. Heterozygous animals can be detected biochemically by their half-normal levels of erythrocyte UMP synthase or by nested polymerase chain reaction (PCR) testing.2,3 Bovine homozygotes die at about the 40th day of pregnancy. Embryonic mortality is the only form of loss.

**HEPATIC LIPODYSTROPHY IN GALLOWAY CALVES**

Hepatic lipodystrophy has been reported in Galloway calves on five farms in the United Kingdom over a 10-year period. Calves appear normal after birth but die by 5 months of age. Clinically there is tremor, opisthotonus, and dyspnea before affected calves become recumbent and die. At necropsy the liver is enlarged, pale, and mottled. Histologically there is evidence of hepatic encephalopathy. The cause is unknown, but limited evidence suggests a storage disease is possible.

**EQUINE PITUITARY PARS INTERMEDIA DYSFUNCTION (FORMERLY EQUINE CUSHING DISEASE)**

Equine pituitary pars intermedia dysfunction (PPID) is a slowly progressive neurodegenerative disease of older equids caused by nonmalignant hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland. It is characterized in its most severe form by hirsutism, laminitis, polyuria, and polydipsia.

**ETIOLOGY**

The pars intermedia of equids is composed of a single cell type—melanotropes—which are innervated by dopaminergic neurons of the periventricular nucleus. Innervation by these neurons is inhibitory on secretion by the melanotropes of proopiomelanocortin (POMC)-derived peptides. Thyrotropin-releasing hormone stimulates melanotropes.¹ The pars distalis of the pituitary gland releases adrenocorticotropic hormone (ACTH) in response to, among other stimuli, declines in plasma cortisol concentration. Cortisol exerts negative feedback on secretion of ACTH by the pars distalis, but not by the pars intermedia.² The disease is attributable to degeneration of the periventricular hypothalamic dopaminergic neurons with subsequent development of a nonmalignant functional tumor comprising of melanotropes of the pars intermedia of the pituitary gland.³ Cushing syndrome caused by adrenocortical tumors is exceedingly rare in equids.

**EPIDEMIOLOGY**

The disease is being diagnosed with increasing frequency. The prevalence of the disease is not well documented, but surveys of owners indicate hair-coat abnormalities consistent with the disease in 15% to 39% of aged equids. Of 200 randomly selected equids 15 years of age or older in the United Kingdom, 22% had hair-coat abnormalities suggestive of PPID detected during an isoglycemic clamp procedure.¹ It is unclear if the abnormal glucose metabolism detected during an isoglycemic clamp procedure is related to PPID and metabolic syndrome, but it is apparent that there should not be an assumption of abnormal glucose metabolism in all equids with PPID.²

**PATHOGENESIS**

PPID is a neurodegenerative disease in which there is a loss of the inhibitory effect of dopamine with subsequent hypertrophy and hyperplasia of melanotropes of the pars intermedia of the pituitary gland with unchecked secretion of proopiomelanocortin and compression of the neurohypophysis. Hirsutism, polydipsia, and optic chiasma.³ Production of proopiomelanocortin by melanotropes in the pars intermedia is not under the negative feedback control of glucocorticoids, and as a result, affected equids produce large quantities of POMC, melanocyte-stimulating hormone(α-MSH), β-endorphin, and smaller but still excessive quantities of ACTH. Production of ACTH results in loss of the normal circadian rhythm in serum cortisol concentration.⁴ The space-occupying effects of the tumor can cause blindness because of compression of the optic chiasma. Polyuria and polydipsia are common and are probably related to neurohypophyseal dysfunction and compression of the pars nervosa, the source of antidiuretic hormone.⁵ Not all equids with PPID have impaired glucose metabolism.⁶ A proportion of horses, estimated as ~40%, with PPID have evidence of abnormal glucose metabolism, including hyperinsulinemia, hyperglycemia, or both, although only 20% have evidence based on results of an IV glucose and insulin test.⁷ Furthermore, horses with PPID do not have abnormalities in glucose metabolism detected during an isoglycemic clamp procedure.¹ It is unclear if the abnormal glucose metabolism and hyperinsulinemia are attributable to PPID or concurrent equine metabolic syndrome, but it is apparent that these abnormalities in glucose metabolism in all equids with PPID.

**CLINICAL FINDINGS**

Affected equids exhibit one or more findings of hirsutism, hyperhidrosis, polyuria, polydipsia, polypagia, muscle atrophy (sarcopenia), laminitis, and docile demeanor.

Hirsutism is a clinical sign with high specificity (95%) for the disease,⁷ meaning that aged equids with hirsutism are likely to have PPID.

Facts about the disease:

1. Hirsutism is a clinical sign with high specificity (95%) for the disease.
2. Polydipsia, polyuria, and polyphagia (diabetes mellitus) are common.
3. Muscle atrophy and lipodystrophy are common.
4. Laminitis and aciology may be present.
5. Equids exhibit one or more findings of hirsutism, hyperhidrosis, polyuria, polydipsia, polypagia, muscle atrophy (sarcopenia), laminitis, and docile demeanor.

Facts about diagnosis:

1. Adrenocorticotropic hormone (ACTH) test is used to confirm diagnosis.
2. Hormonal analysis can be done by radioimmunoassay or radioimmunoassay.
3. ACTH test is used to confirm diagnosis.

Facts about treatment:

1. Treatment is aimed at controlling symptoms and managing complications.
2. Medications such as glagaglandin, insulin, and corticosteroids may be used.
3. Dietary modifications and weight management are important.
4. Equids may require long-term management and monitoring.

Embryonic mortality is the only form of loss.

REFERENCES
have the disease and that there will be few false-positive diagnoses when hirsute aged equids are considered to have PPID. Equids with an owner-reported history of hirsutism are 7.8 times (95% CI, 3.7 to 16.6) more likely to have PPID than are nonhirsute equids of similar age. Hirsutism is characterized by delayed or absent seasonal moulting resulting in a long, shaggy hair coat. There can be some thinning of the coat color. The changes in hair coat are a result of equids with PPID having a greater proportion of hair follicles in the anagen phase (95% of hair follicles on the neck) than healthy equids (15%). Abnormalities of hair follicles resolve and resumption of moulting occurs with administration of pergolide.

Polyuria and polydipsia are common clinical signs in equids with PPID and are likely secondary to diabetes insipidus and not to hyperglycemia. Administration of desmopressin reduces polyuria and polydipsia.

Hyperhidrosis is reported in affected equids, although it does not appear to have been quantified. Equids with PPID in hot environments can be anhidrotic, and this resolves with treatment of the PPID.

Myopathy associated with PPID is characterized by atrophy of type 2 (slow-twitch) fiber types consistent with sarcopenia. Plasma activity of muscle-derived enzymes is not greater in equids with PPID than in healthy aged-matched equids. The molecular basis for muscle atrophy in equids with PPID has been investigated, but the mechanism remains unclear.

There is often central obesity, characterized by excessive fat deposition in the crest of the neck and in the supraorbital fossae, but this is likely a reflection of comorbidity with equine metabolic syndrome rather than a characteristic of PPID. One report demonstrates insulin resistance in equids with PPID using the euglycemic-hyperinsulinemic clamp technique, but this is not a consistent finding. However, equids were not screened for hyperinsulinemia before admission to the study and were selected from a population of equids referred for treatment of laminitis, among other diseases. These equids might well have had both equine metabolic syndrome (EMS) and PPID. Further evidence to support this comorbidity is that plasma fructosamine concentrations are not different between nonlaminitic equids with PPID and healthy controls (reference interval of 195.5 to 301.9). Equids with PPID and laminitis have plasma fructosamine concentrations that are higher than those of animals with PPID but not laminitis.

Fructosamine is a reflection of average blood glucose concentrations over a period of weeks, and higher values are indicative of hyperglycemia.

Laminitis is common in equids with PPID (see “Laminitis of Horses,” Chapter 15). However, it is unclear if this is a result of PPID or comorbidity with EMS.

Rarely, affected equids are blind or have seizures. Affected equids are often infertile and heal poorly. Equids with PPID are considered immunosuppressed and susceptible to development of opportunistic infections and parasitism.

Computed tomography allows measurement of the size of the pituitary gland of equids that correlates well with that measured postmortem. The size of the pituitary gland can be evaluated antemortem.

The outcome is favorable in that 50% of equids are alive 4.6 years after diagnosis, most owners are satisfied with the equid’s quality of life, and most (28/29; 97%) would treat a second equid with the disease. In a study of cases diagnosed between 1993 and 2002, the cause of death among equids (15/20; 85%) was euthanasia, and 11/15 (73%) were euthanized because of conditions associated with PPID.

**CLINICAL PATHOLOGY**

There are no characteristic findings on serum biochemical testing or hematology. Resting serum cortisol concentrations of affected and healthy equids are similar and not useful in diagnosis.

**DIAGNOSTIC CONFIRMATION**

**Antemortem diagnosis of PPID** is not simple and is achieved on the basis of clinical signs and results of one or more of several diagnostic tests. It is important that testing be based on the presence of clinical signs compatible with the disease to minimize the frequency of false-positive diagnoses. Laboratory tests for the disease are not failproof, and the results of these tests should be viewed only in the context of the equid’s clinical signs. Further complicating diagnosis of equine pars intermedia dysfunction is the slow and progressive onset of the disorder. It is therefore likely that attempting a definitive dichotomous answer (disease present or disease absent) based on laboratory testing is unreasonable—some mildly affected equids will test normal, and, less commonly, some apparently healthy equids with histologically normal pituitary glands will test positive. Repeated testing is warranted when test results are ambiguous or not consistent with clinical signs (primarily hirsutism).

Assessment of the utility of the various diagnostic tests is prevented by the lack of a gold-standard diagnosis, except for postmortem examination. Determination of sensitivity and specificity of laboratory tests, or clinical signs, is therefore difficult. Furthermore, antemortem testing is complicated by the seasonal and circadian variations in pituitary function with consequent changes in “resting” or basal serum or plasma concentrations of many analytes. Furthermore, plasma concentrations of some analytes, including ACTH, are affected by feeding.

The changes in pituitary function with season are a recognized physiologic phenomenon related to preparing or adapting physiologic functions to colder conditions and shorter days. This phenomenon was not generally recognized before about 2005, and reports of the characteristics of diagnostic tests before that date should be interpreted with caution.

**Laboratory tests** used to diagnose pars intermedia dysfunction include measurement of serum or plasma cortisol, ACTH, glucose, or insulin concentrations; the ACTH stimulation test; the thyrotropin-releasing hormone stimulation test; administration of domperidone with subsequent measurement of plasma ACTH; measurement of urinary and salivary corticoid concentrations; and combinations of these tests (Table 17-8). The most widely accepted laboratory tests are the overnight dexamethasone suppression test and measurement of serum ACTH concentrations. Other tests have been suggested, but either their sensitivity and specificity have not been determined or they involve measurement of multiple variables or of hormones for which assays are not readily commercially available. Measurement of basal serum insulin concentration is not a useful diagnostic test for equine pars intermedia dysfunction. Measurement of urine or salivary cortisol concentrations has been suggested as a means of diagnosing equine pars intermedia dysfunction, but neither has been validated in a sufficient number of equids to permit assessment of their clinical utility.

One of the first diagnostic tests developed was the overnight dexamethasone suppression test. After collection of a serum sample for measurement of cortisol, dexamethasone (40 µg/kg IM) is administered at about 5 p.m. A second blood sample is collected 15 hours later, with the option to collect a third sample 19 hours after dexamethasone administration. Normal horses will have a serum cortisol concentration of less than 1 µg/dL (28 nmol/L) in the second and third blood samples, whereas affected horses will not show a significant reduction in serum cortisol concentration from that of the initial sample. The sensitivity and specificity of this test are apparently high, with both reported in earlier studies to be approximately 100%. However, recent studies of healthy horses demonstrate that there is considerable seasonal variation in the dexamethasone suppression test, with all of 39 healthy aged ponies and horses having normal tests in January (winter) but 10 of the same 39 (26%) having abnormal tests in September (autumn), and that the test is specific but not sensitive. These results suggest that these diagnostic tests should be interpreted with caution when conducted in the autumn.

Measurement of plasma adrenocorticotropic hormone (ACTH) concentration has been widely accepted as a useful laboratory indicator of equine pars intermedia dysfunction. The plasma ACTH concentration varies with the age of the horse and with the season.
of the year in both the northern and southern hemispheres, but not between ponies and horses. 1, 2 The upper reference intervals of plasma ACTH for healthy horses in the United Kingdom in one report were 29 pg/mL between November and July and 47 pg/mL between August and October. 20 The reference intervals were obtained by sampling a convenience sample of hospitalised horses. A similar pattern is detected in the eastern and southern United States, with the autumnal peak in ACTH occurring earlier in horses in more northern locations. 1, 29, 30 This circannual variation in plasma ACTH occurs in both non-PPID and PPID horses, with PPID horses having higher concentrations than non-PPID horses at all times. 10, 12, 25, 26, 33, 34 Furthermore, the increase in plasma ACTH concentrations stimulated by administration of thyrotropin-releasing hormone (1 mg IV) to healthy horses is greater in autumn and summer than in late winter. 23, 27 These results demonstrate the need for including consideration of season (photoperiod) and latitude when assessing the diagnostic importance of plasma ACTH concentrations in aged horses. It is prudent to use reference intervals developed in local laboratories or in distant laboratories with knowledge of the reference interval for the particular geographic location (latitude) and season of the horse. 20 There is no circadian rhythm to ACTH concentrations in horses with PPID, but there is conflicting evidence of a circadian rhythm in healthy horses. 10, 35, 36 It appears that ACTH concentrations of horses are highest at 0800 hours and then decline over the day, although the changes are small and not likely to affect clinical interpretation of plasma ACTH concentrations. 35 There is not an ultradian rhythm (periodic changes during a 24-hour period) in plasma ACTH

<tbody>
<tr>
<td>Overnight DEX suppression</td>
<td>Collect serum between 4 and 6 p.m. Administer DEX at 40 µg/kg BW IM. Collect serum 19–20 hours later.</td>
<td>2 serum samples, 1 mL each; 1 pre-DEX administration and 1 post-DEX administration</td>
<td>Serum control of &gt; µg/dL at 19 hours post-DEX administration suggests PPID.</td>
<td>A mildly decreased resting cortisol (pre-DEX administration) is typical of a PPID-affected horse. A resting cortisol of &lt; 1.8 µg/dL is suggestive of iatrogenic adrenal insufficiency.</td>
</tr>
<tr>
<td>Endogenous plasma ACTH concentration</td>
<td>Collect EDTA plasma, preferably in plastic blood-collection tube. Separate plasma by centrifugation, and freeze for submission to laboratory. Avoid hemolysis and heat. Process sample within 8 hours of collection.</td>
<td>EDTA plasma sample, 1 mL</td>
<td>Normal reference range depends on methodology and laboratory. Typically an ACTH concentration &lt; 35 pg/mL (chemiluminescent immunoassay) or &lt; 45–50 pg/mL (radioimmunoassay) is considered normal.</td>
<td>ACTH is likely affected by many biologic events, all of which are not well documented at present. Seasons can have a profound effect, with higher concentrations seen in autumn.</td>
</tr>
<tr>
<td>Endogenous plasma α-MSH concentration</td>
<td>Collect EDTA plasma, preferably in plastic blood-collection tube. Separate plasma by centrifugation, and free for submission to laboratory. Avoid hemolysis and heat. Process sample within 8 hours of collection.</td>
<td>1 EDTA plasma sample, 1 mL</td>
<td>Nonautumn reference range: &gt; 35 pmol/L suggests PPID.</td>
<td>Plasma α-MSH concentration is extremely seasonal. High concentrations are observed in autumn.</td>
</tr>
<tr>
<td>TRH stimulation assay</td>
<td>Collect serum. Administer TRH, 1 mg IV. Collect serum 30–60 minutes after TRH.</td>
<td>2 serum samples, 1 mL each; pre-TRH administration, 30 minutes post-TRH administration, and 24 hours post-DEX administration</td>
<td>30%-50% increase in serum cortisol 30 minutes after TRH administration suggests PPID.</td>
<td>Pharmaceutical TRH is expensive; TRH compounded for this use may be difficult to obtain. False-positive results may be common.</td>
</tr>
<tr>
<td>Combined DEX suppression/ TRH stimulation test</td>
<td>Collect plasma between 8 and 10 a.m. Administer DEX at 40 µg/kg BW IM. Administer TRH, 1 mg IV, 3 hours after DEX administration. Collect serum 30 minutes after TRH and 24 hours after DEX administration.</td>
<td>3 plasma samples, 1 mL each; pre-DEX administration, 30 minutes post-TRH administration, and 24 hours post-DEX administration</td>
<td>Plasma cortisol &gt; 1 µg/dL at 24 hours post-D EX administration or ≥ 66% increase in cortisol levels 3 hours after TRH administration suggests PPID.</td>
<td>Some diagnostic laboratories prefer to use serum for measurement of cortisol levels. The effect of season on the combined test has not been assessed but would likely result in false-positive results as each of the component tests do.</td>
</tr>
<tr>
<td>Domperidone response test</td>
<td>Collect EDTA plasma at 8 a.m. Administer domperidone at 3.3 mg/kg BW po. Collect EDTA plasma at 2 and 4 hours after domperidone administration.</td>
<td>3 EDTA plasma samples, 1 mL each</td>
<td>A twofold increase in plasma ACTH concentration suggests PPID.</td>
<td>Higher doses (5 mg/kg po) may improve response. The 2-hour sample is more diagnostic in the summer and autumn, and the 4-hour sample is best in the winter and spring.</td>
</tr>
</tbody>
</table>

administration, whereas serum cortisol concentrations in horses with equine pars intermedia dysfunction increase by more than 66% of the baseline value.

Plasma fructosamine concentrations do not differ between healthy horses (range 195.5 to 301.9 mu mol/L) and horses with PPID. Plasma insulin concentrations are increased in a proportion of horses with PPID and are suggested to be indicative of the risk of laminitis in these horses (see discussion of equine laminitis, Chapter 15).39,41

**NECROPSY FINDINGS**

The pituitary gland is usually enlarged as a result of the increased numbers of melanocortin cells comprising an adenoma of the pars intermedia. The adenal cortices are usually of normal width, but they may be thickened in some cases. With the appropriate clinical history, the observation of a well-defined nodule within the pituitary gland is usually sufficient for confirmation of the diagnosis, but histology and immunohistochemical testing of the mass can be performed. There is only fair (kappa = 34%) agreement among pathologists for histologic diagnosis of the disease.

**DIFFERENTIAL DIAGNOSIS**

- Insulin resistance
- Diabetes insipidus (nephrogenic)
- Both of these diseases are exceedingly rare in horses
- Obesity
- Psychogenic polydipsia or salt eating
- Chronic renal failure

**TREATMENT**

Treatment is palliative and not curative in that clinical signs can be controlled by administration of pergolide, but the underlying neurodegenerative disease is not cured. The aim of treatment is to reduce secretion of the products of the melanotropes through the use of dopamine agonists or serotonin antagonists. Treatment must be continued for the life of the horse or pony.

The treatment of choice is administration of pergolide mesylate, a dopamine agonist, at 1.7 to 5.5 µg/kg orally every 24 hours. The recommended starting dose is 2.0 to 3.0 µg/kg once daily for 2 months, at which time clinical (hirsutism) and laboratory (plasma ACTH concentration) signs of the disease should be evaluated. The dose can be escalated by 1-µg/kg increments until control of clinical signs is achieved.

Pergolide mesylate is rapidly absorbed after oral administration to fasted mares with a time to maximum drug concentration in plasma of 0.4 hours, maximum concentration of 4 ± 2 ng/mL, and terminal elimination half-life estimated to be 5.9 ± 3.4 hours. Care should be exercised in the storage of pergolide mesylate compounded in an aqueous vehicle because it is susceptible to degradation if exposed to heat, light, or both. Compound pergolide formulations in aqueous vehicles should be stored in a dark container, protected from light, and refrigerated, and it should not be used more than 30 days after production. Formulations that have undergone a color change should be considered degraded and discarded.44 A commercial form of pergolide mesylate formulated for use with horses and ponies (Prascend®) is available in some countries. Cyproheptadine, a serotonin antagonist, is administered at 0.25 mg/kg orally every 24 hours for 1 month. If an acceptable response is achieved, then this dose is continued; if not, then the dose is increased to 0.25 mg/kg every 12 hours. This drug is now rarely used in the treatment of PPID. Symptomatic treatment should include clipping of the hair coat in spring, treatment of laminitis and wounds, prevention of injuries and infection, and dietary management to reduce hyperglycemia in those animals with this abnormality documented (see “Equine Metabolic Syndrome”), in addition to maintenance of optimal body weight. Some equids with PPID lose weight and require careful nutritional management.

**REFERENCES**

Insulin resistance is defined as abnormally depressed insulin-mediated glucose transport into insulin-sensitive cells (adipose tissue, skeletal muscle). EMS is the clinical syndrome, whereas insulin resistance in an underlying metabolic abnormality.

**ETIOLOGY**

EMS likely has important genetic determinants, with manifestation of the syndrome when susceptible animals, by virtue of their genetic composition, are exposed to environmental conditions that favor or enable development of the disease. This is thought to be similar to the situation with human metabolic syndrome or type 2 diabetes. It is speculated that breeds of equids that evolved under conditions of frequent restriction of energy intake, such as during long winters, are genetically predisposed to have efficient energy metabolism that under modern management systems can result in obesity and development of insulin resistance.1

**EPIDEMIOLOGY**

The epidemiology of EMS is not well described, and there are few studies that have identified the frequency of the condition, using established case definitions, in large numbers of horses or ponies. Consequently, there is little evidence on outcome (morbidity, case-fatality rates, all-cause morbidity, specific-cause mortality) in horses and only anecdotal information on breed, age, and sex as risk factors. Twenty seven percent (51/188) of ponies of various breeds examined in Australia were hyperinsulinemic (>20 μu/mL) after ponies with documented PPID (see previous section) were excluded.1 There is somewhat more information regarding the epidemiology of obesity in horses, but it should be recognized that not all obese horses are insulin resistant (and therefore do not fit the definition of EMS).4,5 Similarly, there is information on the epidemiology of pasture-associated (endocrinopathic) laminitis (see “Laminitis of Horses,” Chapter 15), and from this one can infer risk factors for insulin resistance and EMS.

Horses or ponies of different breeds but similar body weight differ in their insulin resistance, and there is consensus that particular breeds are at increased risk of EMS; these include ponies (of any of the common breeds), Morgan Horses, Paso Fino, Andalusian, Arabian, Saddlebred, Quarter Horses, Tennessee Walking Horses, and Warmblood Horses.1,3 It appears that some light breeds such as Standardbreds and perhaps Thoroughbreds are at reduced risk. The frequency of the condition increases with age in ponies,1 and sex does not appear to be a risk factor. There is a seasonality to the occurrence of pasture-associated laminitis,6 and this might represent seasonal changes in energy intake (from pasture) of susceptible animals rather than seasonal variations in severity of insulin resistance. However, there is evidence that measures of insulin resistance in horses and/or ponies vary depending on season, with declines in insulin sensitivity of ponies in summer. Insulin sensitivity, defined using the combined insulin and glucose intravenous test and serum insulin concentrations are not related to season in healthy, mature horses.8,9

Obesity is common in domestic horses, with studies in Scotland and the eastern United States finding that 45% and 19%, respectively, of horses were considered obese.10,11 Although interpretation of both studies is limited by the localized nature of the sampling and restrictions on the types of horses included, these studies do support a wider consensus that obesity is common in horses. Chronic intake of energy in excess of maintenance needs (overeating) and insufficient exercise are thought to be risk factors, or inciting factors, for obesity.

**PATHOGENESIS**

EMS is primarily a manifestation of insulin resistance, and insulin resistance is often, but not always, associated with obesity. The syndrome likely includes abnormalities in energy metabolism, adipocyte function, hemostasis (thrombosis), inflammation, response to lipopolysaccharide (endotoxin) exposure, and oxidant stress.1,2 The pathogenesis of laminitis associated with EMS (“endocrinopathic laminitis”) is discussed elsewhere.

Insulin resistance is the decreased rate of transport of glucose into cells of glucose-sensitive tissues in response to exposure to insulin. Horses with insulin resistance have lesser reductions in blood glucose concentration in response to administration of insulin than do insulin-sensitive horses.13,14 Insulin-stimulated glucose transport is achieved by GLUT-4 (glucose transporter protein 4, which is one of at least 12 glucose transporter proteins) when it is present on the surface of insulin-sensitive cells. Horses with insulin resistance have abnormal glycemic and insulinemic responses to oral or IV administration of glucose or oral administration of sugar (see following discussion) and have reduced concentrations of GLUT-4 on the surface of adipose tissue.15,16 Insulin resistance in horses is associated with an exaggerated response in plasma/serum insulin concentration after administration of glucose. This exaggerated response allows maintenance of resting blood glucose concentrations in the reference range in affected horses—so-called compensated insulin resistance.1

Insulin resistance in humans is currently thought linked to inflammation induced by macrophage activation in adipose tissue, and there is increasing evidence of a similar mechanism in equids.18 The BCS of horses is also correlated with both plasma insulin concentration and serum amyloid A.
concentration (an acute-phase protein indicative of inflammation). There are only minimal effects of insulin infusion (6-hour duration) on tumor necrosis factor alpha and interleukin(IL)-6 concentrations in the plasma of healthy horses, and no association has been found between BCS or insulin concentration and plasma concentrations of tumor necrosis factor and IL-6. Horses with EMS have prolonged inflammatory responses (evidenced by plasma IL-8, IL-10 and tumor necrosis factor concentrations) to infusion of endotoxin compared with healthy horses, although the clinical importance of this observation is unclear. Horses with EMS have a marked increase in neutrophil reactive oxygen species production induced by phagocytosis that is strongly correlated to the blood insulin concentration.

In contrast, peripheral blood cells of obese hyperinsulinemic horses showed decreased endogenous proinflammatory cytokine gene expression (IL-1 and IL-6) and similar cytokine response following immune stimulation compared with that of control horses. The authors conclude that this could suggest that, unlike in people, cytokine-mediated inflammation does not increase in direct response to obesity or insulin resistance in horses.

Mechanisms underlying obesity and regional adiposity are unclear, but at the most fundamental level involve an excess of energy intake over energy expenditure, with deposition of the net excess energy as fat. As discussed previously, some horses and ponies appear to be much more efficient at converting feed into energy, or at regulating energy use, with the result that it is challenging to achieve a reduction in the weight of these animals even with strict control of food intake. The genetic or hormonal causes of this resistance to weight loss are unclear, although it is apparent that some horses and ponies have an exaggerated insulimetic response to ingestion of soluble carbohydrate. This exaggerated response could be the underlying mechanism for hyperinsulinemia, obesity or regional adiposity, and endocrinopathic laminitis.

Adipose tissue is an important source of hormones regulating energy metabolism and of inflammatory cytokines. Obesity, or “over-conditioning,” in horses (as assessed by BCS) is associated with higher plasma insulin and leptin concentrations than in optimally conditioned horses. Obese horses also have higher triglyceride concentrations and lower red blood cell glutathione peroxidase activities (an indication of antioxidant capacity) than optimally conditioned horses.

Regional obesity is an important risk factor in humans for metabolic syndrome and might be similarly so in horses and ponies. Visceral fat is important in humans, but it appears to be less so in horses, with nuchal ligament fat (which contributes to the cresty neck characteristic of affected horses and ponies) having greater proinflammatory gene expression (IL-1β and IL-6) in affected horses, although others, using measurement of other markers of inflammation, find that the omental and retroperitoneal (visceral) fat of insulin-resistant horses have greater expression of markers of inflammation (Toll-like receptor 4 and suppressor of cytokine signaling 3 [SOCS-3]) than do insulin-sensitive horses. Finally, there is evidence of regional differences in glucose transport by adipose tissue, with omental adipose tissue having the highest total GLUT content compared with subcutaneous and nuchal ligament fat in healthy horses, but having a reduced total GLUT4 content and cell surface expression in insulin-resistant horses.

**CLINICAL SIGNS**

Equine metabolic syndrome is defined by obesity (with or without regional adiposity), insulin resistance, and increased susceptibility to laminitis. As such, only obesity and regional adiposity and clinical signs of active or past laminitis are physical evidence of the presence of metabolic syndrome. Affected ponies can be hypertensive.

Clinical assessment of obesity/adiposity is achieved by use of body-condition scoring, measurement of subcutaneous or retroperitoneal fat by ultrasound, and grading of regional adiposity. Methods used for research studies include slaughter and dissection with proximate analysis of body constituents or measurement of the deuterium dilution space (volume of distribution) in living animals. Bioelectrical impedance can be used to measure body-water content, but it has not achieved widespread clinical acceptance. Measurement of body weight is not useful for assessment of obesity or adiposity because body weight is highly correlated with height and girth and does not provide an accurate indication of body fat.

A number of body-condition scoring systems have been developed, and the two most commonly used are those of Henneke (later modified by various authors), which uses a 1-to-9 grading system (Table 17-9 and Fig. 17-7), and Carroll and Huntington, which uses a 1-to-5 grading system. These grading systems were not developed to assess the fat content (proportion) of horses, but rather to assess “flesh” or the general body condition. Both systems have limitations, including their subjective nature and the fact that they have not been validated in all breeds and body types of horses (validation determines the relationship between BCS and a gold-standard measure of body fat, such as deuterium dilution space or carcass analysis), nor has their reliability (intrarater and interrater agreement/repeatability expressed as an intraclass correlation coefficient or, less optimally, a kappa or weighted-kappa statistic) been demonstrated over large numbers of raters. There are reports of an intraclass correlation coefficient (ICC) of 0.74 for four raters of 21 mares and 75 ponies, but details are not provided. Another reports an ICC of 0.92, but without details to allow assessment of the methodology. Additionally, body-condition scoring systems do not provide an assessment of regional adiposity, which might have greater clinical relevance.

BCS (1-to-9 scale) correlates well with percent body fat (TBF) when both are log transformed (eTBF = 0.006 + e0.50BCS). In practical terms, this means that the accuracy of this body-condition scoring system to predict the proportion of body fat declines as BCS increases—for example, the proportion of body fat varies from ~13% to 36% in horses with a BCS of 7 to 8/9. The log-log BCS model correctly predicted body fat greater than 20% (BCS = 6.83) in 76% of horses and with sensitivity of 83% and specificity of 71%. However, the need to use log-log transformation decreases the general utility of this technique.

Body-condition scoring is a demonstrably insensitive measure of changes in body fat—ponies subject to 11% reduction in body weight and a 45% reduction in body fat did not have a change in BCS.

Body-condition scoring systems have been developed for use with ponies and horses. The ICC (a measure of reliability between raters) is 0.70 for four raters of 21 mares and 75 ponies. The “cresty neck score” correlates well with plasma insulin and glucose concentrations in pooled horse and pony data, and with insulin, leptin, and triglyceride concentrations when horses and ponies are considered separately. Additionally, ponies with a cresty neck score of 4 or greater are at increased risk of developing pasture-associated laminitis. This scoring system therefore appears to be both reliable (good interrater agreement) and indicative of clinically meaningful variables and outcomes (Table 17-10).

Acute laminitis and residual signs of laminitis (sometimes call chronic laminitis) are common in animals with insulin resistance and provide the physical confirmation of EMS in these animals. Clinical signs of laminitis are described under that topic (Chapter 15).

**Diagnosis**

Definitive diagnosis of EMS of horses in the field is achieved by demonstration of insulin resistance in equids with appropriate clinical signs (obesity, regional adiposity, laminitis) and is confirmed by measurement of plasma concentrations of glucose and insulin.
Insulin resistance can be detected by use of measurement of insulin and glucose concentrations in a single blood sample (point testing) or by more sophisticated testing using measurement of these analytes on multiple occasions after administration of glucose and insulin to equids (dynamic testing)—either as the euglycemic clamp technique or the frequently sampled intravenous glucose and insulin test (minimal model). The former has greater utility in clinical and field settings, although with the potential for reduced sensitivity and/or specificity, whereas the latter is useful for research or referral settings and is regarded as the gold standard for diagnosis.

Hyperglycemia is rarely detected in equids with insulin resistance, and measurement of blood glucose concentrations alone is not a useful test for detection of insulin resistance. Detection of persistent, inappropriate hyperglycemia (i.e., that not associated with stress or ingestion of food) should prompt consideration of diabetes mellitus. Hyperinsulinemia in the absence of conditions that increase insulin secretion (stress, pain, feeding) is strong evidence of the presence of insulin resistance. Interpretation of plasma or serum insulin concentrations must include consideration of a number of factors that could affect the actual concentration reported by the laboratory. Physiologic factors that can increase serum insulin concentration include feeding, stress and pain, and administration of alpha-2 adrenergic agonists (xylazine, detomidine, romifidine, etc.). Feeding increases plasma insulin concentration in both healthy and insulin-resistant horses and confounds interpretation of the results of testing. Pain and stress increase both plasma glucose and insulin concentrations through increases in cortisol and epinephrine concentrations in blood, which decrease insulin sensitivity. This could be important when testing equids with active laminitis or other causes of pain—evaluation should be delayed until the pain is resolved.

<thead>
<tr>
<th>Score</th>
<th>Condition</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Poor</td>
<td>Animal is extremely emaciated. Spine, tailhead, hooks (tuber coxae; hip joints), and pins (tuber ischia; lower pelvic bones) projecting prominently. Bone structure of withers, shoulders, and neck easily noticeable. No fatty tissue can be felt.</td>
</tr>
<tr>
<td>2</td>
<td>Very thin</td>
<td>Animal is emaciated. Slight fat covering over base of spinal processes, transverse processes (portions of vertebrae that project outward) of lumbar (loin area) vertebrae feel rounded. Spinal processes, ribs, tailhead, hooks, and pins are prominent. Withers, shoulders, and neck structures are faintly discernible.</td>
</tr>
<tr>
<td>3</td>
<td>Thin</td>
<td>Fat is built up about halfway on spinal processes; transverse processes cannot be felt. Slight fat cover over ribs. Spinal processes and ribs are easily discernible. Tailhead is prominent but individual vertebrae cannot be visually identified. Hook bones appear rounded, but are easily discernible. Fat can be felt around tailhead (prominence depends on conformation). Hook bones are not discernible. Withers, shoulders, and neck are not obviously thin.</td>
</tr>
<tr>
<td>4</td>
<td>Moderately thin</td>
<td>Negative crease along back (spinal processes of vertebrae protrude slightly above surrounding tissue). Fat outline of ribs is discernible. Fat can be felt around tailhead (prominence depends on conformation). Hook bones are not discernible. Withers, shoulders, and neck are not obviously thin.</td>
</tr>
<tr>
<td>5</td>
<td>Moderate</td>
<td>Back is level. Ribs cannot be visually distinguished, but can be easily felt. Fat around tailhead begins to feel spongy. Withers appear rounded over spinous processes. Shoulders and neck blend smoothly into body.</td>
</tr>
<tr>
<td>6</td>
<td>Moderately fleshy</td>
<td>May have slight crease down back. Fat over ribs feels spongy. Fat around tailhead feels soft. Fat begins to be deposited along at sides of withers, behind shoulders, and along neck.</td>
</tr>
<tr>
<td>7</td>
<td>Fleshy</td>
<td>May have crease down back. Individual ribs can be felt, but with noticeable filling of fat between ribs. Fat around tailhead is soft. Fat is deposited along withers, behind shoulders, and along neck.</td>
</tr>
<tr>
<td>8</td>
<td>Fat</td>
<td>Crease down back. Difficult to feel ribs. Fat around tailhead is very soft. Area along withers is filled with fat. Area behind shoulder is filled with fat and flush with rest of the body. Noticeable thickening of neck. Fat is deposited along inner thighs.</td>
</tr>
<tr>
<td>9</td>
<td>Extremely fat</td>
<td>Obvious crease down back. Patchy fat appears over ribs. Bulging fat around tailhead, along withers, behind shoulders, and along neck. Fat along inner thighs may rub together. Flank is filled with fat and flush with rest of the body.</td>

considerable cross-reactivity between human and equine insulin. Equine-specific tests are now available, and their precision, accuracy, and specificity have been reported. 45 The gold-standard methodology is liquid chromatography–mass spectrometry (LC-MX), but this is expensive and has limited accessibility in laboratories processing large numbers of clinical samples. Analysis of six commonly used or available test kits for measuring plasma or serum concentrations of insulin demonstrated that none reflected concentrations measured by LC-MS and that only one provided reliable (valid) results—the Siemens Coat-a-Count Insulin Radioimmunoassay (RIA)—and only if samples with concentrations exceeding the highest standard were diluted with charcoal-stripped plasma and not the provided diluents. 45

The effect of use of differing methods of measuring serum insulin concentration is that use of “cutoff” values for detecting insulin resistance provided by different laboratories is problematic. A value of 20 µU/mL is recommended as a cutoff, measured using the Siemens Coat-a-Count Insulin RIA, for defining insulin resistance. 4 However, this value should be interpreted with caution because the sensitivity (proportion of false negatives) and specificity (proportion of false positives) are not reported, and the test as a way of defining insulin resistance has not been well validated. It can be a useful screening test. 4 Local laboratories should be contacted before testing to determine the test used and whether the laboratory has determined reference ranges for its testing methodology.

Proxy indicators of insulin resistance, derived from measurement of plasma glucose and insulin concentrations, have been proposed and used to define insulin resistance and predict predisposition to laminitis in ponies. 7,40,41,46 A commonly used proxy is the RISQI:

\[
\text{RISQI} = \frac{\text{insulin concentration}}{\text{glucose concentration}}^{0.5}
\]

where lower values of the RISQI indicate lower insulin sensitivity.

Dynamic testing is usually achieved using combined glucose and insulin challenge tests of varying complexity. 1,41 One of these tests measures the insulin and glucose responses to IV’s administration of glucose (150 mg/kg BW) and insulin (0.10 U/kg) with frequent sampling of blood (immediately before and at 1, 5, 15, 25, 35, 45, 60, 75,

---

90, 105, 120, 135, and 150 minutes after infusion). A more complex test, involving the frequent sampling of blood and delayed administration of insulin, is analyzed using the “minimal model” and yields four measures of insulin sensitivity, glucose disposal, and insulin secretion (pancreatic response).

Dynamic testing can also involve the administration of insulin and monitoring of blood (plasma) glucose concentrations. A modified test involves administration of 0.1 U/kg IV of recombinant human insulin and measurement of blood glucose concentrations immediately before and 30 minutes after. Insulin-sensitive horses (n = 6 in the study) all had a 50% or greater reduction in blood glucose concentrations 30 minutes after insulin administration, whereas none of the insulin-resistant horses (n = 6) had this response. The sensitivity and specificity of this test need to be determined in larger numbers of healthy and insulin-resistant horses for it to be clinically useful.

An oral sugar test (OST) provides results as reliable as the IV glucose tolerance test for detection of insulin resistance and hyperinsulinemia. The test involves oral administration of 0.15 mL/kg of corn syrup (approximately 150 mg/kg BW of dextrose-derived digestible sugars) to equids after an overnight fast. Plasma insulin and glucose concentrations are measured immediately before and 30, 60, and 90 minutes after administration of corn syrup. Equids with EMS have higher glucose and insulin concentrations than do unaffected horses.

**CLINICAL PATHOLOGY**

Clinical pathology includes detection of hyperinsulinemia (as noted in the previous discussion), hyperleptinemia, hypertriglyceridemia, and normoglycemia. Plasma ACTH concentrations of horses with EMS are within the reference range for healthy horses, noting that horses with EMS might also have PPID.

**NECROPSY**

Affected horses are usually examined postmortem because of laminitis. Other than signs of laminitis and obesity/regional adiposity, there are no other characteristic lesions. The pancreas is normal.

**DIFFERENTIAL DIAGNOSIS**

- Obesity without insulin resistance
- Pituitary pars intermedia dysfunction
- Laminitis of cause other than EMS (systemic septic disease such as colitis or metritis)

**TREATMENT**

The objective of treatment is to improve the insulin sensitivity of affected equids. This can be achieved by reducing the proportion of the body made up of fat through careful dietary control. Administration of insulin-sensitizing drugs is attracting interest, but has yet to be of clearly demonstrated clinical utility.

**Dietary Management**

The fundamental aims of dietary management are as follows:

- Achieve and maintain an ideal BCS (body weight, noting earlier comments that body weight does not indicate body composition).
- Minimize intake of nonstructural carbohydrates because these induce an insulinemic and hyperglycemic response in EMS-affected equids and at-risk animals.
- Ensure an adequate and balanced intake of essential nutrients.

The ideal BCS of ponies has been much mentioned, but little or seldom defined. The ideal body condition for a pony or horse would be one at which it has insulin sensitivity within the reference range (i.e., is not insulin resistant), has plasma triglyceride concentrations within the reference range, and is not at increased risk of laminitis. There is likely no one BCS that meets all of these criteria for all equids, and each animal must be considered in light of its own circumstances and physiology. Monitoring of measures of insulin resistance and plasma triglyceride concentration would provide guidance in achieving the animal’s ideal, or acceptable, body weight.

Achieving and maintaining an acceptable BCS (as a proxy for proportion of body fat) is not easy. Animals at most risk of obesity and regional adiposity are often metabolically equipped to maintain this body condition, and reducing body weight or BCS might not be as simple as just reducing feed intake.

Recommendations for reduction in feed intake suggest that feeding 1.25% of body weight daily as hay is adequate to achieve a gradual reduction in body weight. However, planning a diet to provide a reduction in body weight while ensuring an adequate intake of essential nutrients and providing for the digestive and psychological health of the horse or pony can be challenging.

An initial step must be to eliminate or severely reduce access to pasture. Pasture provides unregulated access to fodder, and ponies can consume 2% to 5% of their body weight in pasture each day. This will result in weight gain. Additionally, pasture, and especially green pasture, has a high content of nonstructural carbohydrates (glucose, starch) that induces a glycemic and hyperinsulinemia response in ponies and susceptible horses. Access to pasture can be eliminated by housing animals on a dry lot or by fitting a grazing muzzle.

Hay can be fed as 1.25% to 1.5% of body mass as dry matter per day. The nonstructural carbohydrate content of the hay should be reduced by soaking it in cold water for 12 to 16 hours before feeding. The water used to soak the hay should not be provided to the horse or pony. Feeding this diet will induce a reduction in body weight and improvement in indices of insulin sensitivity.

Individual horses and ponies can be resistant to weight loss, and a reduction in daily dry matter intake to 1% of body weight might be needed to achieve loss of body weight. However, restriction of intake to this level can cause behavioral changes, such as eating bedding, chewing tails of companions, and other allotriophagia. An early example of dietary restriction inducing allotriophagia was that of Robert Falcon Scott’s use of ponies in an expedition to reach the South Pole. The ponies displayed profound appetite for roughage as a consequence of their highly concentrated ration.

Supplements including chromium have been promoted as improving insulin sensitivity in horses. There is evidence that they are not effective, and there is no evidence of efficacy.

**Exercise**

Exercise increases the insulin sensitivity of horses, and it appears sensible to recommend an increase in the amount of exercise of obese ponies and horses. However, moderate exercise training does not improve the insulin sensitivity of horses. Moderate exercise by nonobese ponies previously affected with laminitis reduced serum amyloid A concentrations, heptogelin concentrations, and postexercise serum insulin concentrations. These results suggest a beneficial role for relatively low-intensity exercise (10 minutes enforced walking followed by 5 minutes of trotting) in reducing inflammation in ponies at risk of laminitis.

**Medications**

Administration of levothyroxine or metformin has been advocated for treatment of EMS. Levthyroxine (0.1 mg/kg orally q24 h) causes weight loss and improves insulin sensitivity in obese horses and is recommended as an adjunct to dietary management.
Metformin, which is used for treatment of type 2 diabetes in people, has been administered to horses in an attempt to improve insulin sensitivity. Although initial reports were favorable, more recent pharmacologic investigation has not demonstrated its efficacy at a dosage of 15 mg/kg orally q12h in improving insulin sensitivity. However, administration of metformin at 30 mg/kg q12h reduced glycosylated and insulinemic responses of healthy horses and horses with dexamethasone-induced insulin resistance to administration of dextrose. Whether this dosage will be effective in horses or ponies with naturally occurring insulin resistance remains to be determined. Pioglitazone has been investigated in healthy horses, in which it does not improve insulin sensitivity at (1 mg/kg q24h for 12 days) or attenuate the effects of endotoxin infusion on indicators of systemic inflammation. However, pioglitazone improves insulin sensitivity in healthy horses and horses with naturally occurring insulin resistance. The pharmacokinetics of pioglitazone in horses have been reported.

**GLYCOGEN BRANCING ENZYME DEFICIENCY IN HORSES**

Glycogen branching enzyme deficiency (GBED) is a fatal condition of fetuses and neonatal foals of the Quarter Horse, Paint Horse, and associated breeds. The disease is caused by a nonsense mutation in codon 34 of the GBE1 gene, which prevents the synthesis of a functional GBE protein and severely disrupts glycogen metabolism. The mutant GBE1 allele frequency in registered Quarter Horse, Paint Horse, and Thoroughbred horses is reported as 0.041, 0.036, and 0.006, respectively. Among 651 elite-performance American Quarter Horses, 200 control American Quarter Horses, and 180 control American Paint Horses, the GBED allele was detected with an overall frequency of 0.054. GBED is inherited as a simple recessive trait from a single founder. The disease is reported in North America and Germany.

Affected foals are aborted, born dead, or affected at birth. It is estimated that up to 2.5% of fetal and early neonatal deaths in Quarter Horses and related breeds are associated with this defect. Foals that are born alive are weak and hypothermic, some have flexural limb deformities, and all die usually within hours to days of birth. Affected foals have refractory hypoglycaemia and minor elevations in serum activity of creatine kinase.

The disease is confirmed by detection of periodic acid–Schiff (PAS)-positive inclusions in the cardiac or skeletal muscle and genotype analysis. There is no effective treatment, and control is by selective and prudent breeding.

**LACTATION TETANY OF MARES (ECLAMPSIA, TRANSPORT TETANY)**

Lactation tetany of mares is caused by hypocalcemia and is characterized by abnormal behavior progressing to incoordination and tetany. The precise cause of the hypocalcemia has not been determined, but the cause of the clinical signs is a marked reduction in serum concentration of ionized calcium. The effect of feeding diets high in calcium, such as alfalfa hay, during late pregnancy, and of abrupt changes in diet after parturition, have not been investigated in horses.
as they have in cattle (see discussion of milk fever).

The disease was most common when draft-horse breeding was widely practiced, but it is uncommon now. \(^1\) The case fatality rate is high in untreated animals. Most cases occur in lactating mares, either at about the 10th day after foaling or 1 to 2 days after weaning. High-producing mares grazing on lush pasture are most susceptible and in many instances are engaged in hard physical work. The housing of wild ponies or prolonged transport can precipitate an episode. The latter has been a particularly important factor in the etiology of the disease in Britain and has been credited with precipitating it even in stallions and dry mares. Occasional cases occur without there being any apparent cause. The disease has occurred in a 20-year-old gelding pony. Hypocalcemia with clinical signs also occurs in horses used for prolonged exercise, such as endurance racing or 3-day events.

Hypocalcemia occurs in other diseases of horses, including colic and colitis, and as a result of hypoparathyroidism. \(^2,3\)

Many mild cases of lactation tetany that recover spontaneously occur after transport, but the case fatality rate in some shipments can be greater than 60%. Mares that develop the disease at the foal heat or at weaning are usually more seriously affected, and the case fatality rate is high if mares are not treated in a timely fashion.

Severely affected animals sweat profusely and have difficulty moving because of tetany of the limbs and incoordination. The gait is stiff, and the tail is slightly raised. Rapid, labored respirations and wide dilatation of the nostrils are often accompanied by synchronous diaphragmatic flutter (“thumps”) evident as a distinct thumping sound from the thorax. Muscular fibrillation, particularly of the masseter and shoulder region, and trismus are evident, but there is no prolapse of the membrana nictitans. Affected animals are not hypersensitive to sound, but handling can precipitate increased tetany. The temperature is normal or slightly elevated, and although the pulse is normal in the early stages, it later becomes rapid and irregular. The mare might make many attempts to eat and drink but appears to be unable to swallow, and passage of a stomach tube can be difficult. Urination and defecation are in abeyance, and peristalsis is reduced.

Within about 24 hours the untreated mare becomes recumbent; tetanic convulsions develop and become more or less continuous. The mare dies about 48 hours after the onset of illness. The tetany and excitement in the early stages suggest tetanus, but there is no prolapse of the third eyelid, and there is the usual relationship to recent foaling or weaning and physical exertion. The anxiety and muscle tremor of laminitis can be confused with those of lactation tetany, especially when it occurs in mares that have foaled and retained the placenta. Pain in the feet and bounding digital pulses are diagnostic features of this latter disease.

Hypocalcemia occurs with serum concentrations in the range of 4 to 6 mg/dL (1 to 1.50 mmol/L), and the degree of hypocalcemia has been related to the clinical signs. When serum calcium levels are higher than 8 mg/dL (2 mmol/L), the only sign is increased excitability. At levels of 5 to 8 mg/dL (1.25 to 2 mmol/L), there are tachic spasms and slight incoordination. At levels of less than 5 mg/dL (1.25 mmol/L), there is recumbency and stupor. It is the concentration of ionized calcium that is important, and some animals, such as horses used for 3-day events, can have normal total calcium concentrations but abnormally low ionized calcium concentrations as a result of changes in acid-base status. If possible, serum concentrations of ionized calcium should be measured in horses with clinical signs suggestive of hypocalcemia. Hypomagnesemia with serum magnesium levels of 0.9 mg/dL (0.37 mmol/L) has been observed in some cases, but only in association with recent transport. Hypermagnesemia has been reported in other cases.

Treatment by IV administration of calcium borogluconate as recommended in the treatment of parturient paresis in cattle results in rapid, complete recovery. The dose for a 500-kg mare is 300 to 500 mL of a 25% solution of calcium borogluconate or gluconate administered slowly (over 15 to 30 min) intravenously. One of the earliest signs of recovery is the voiding of a large volume of urine. Occasional cases that persist for some days have been recorded.

**REFERENCES**

**EQUINE HYPERLIPEMIA**

**SYNOPSIS**

**Etiology** Abnormal energy metabolism secondary to inadequate caloric intake.

**Epidemiology** Pregnant or lactating middle-aged, overweight ponies, donkeys, and American miniature horses. Worldwide.

**Sporadic.**

**Clinical signs** Depression, anorexia, weight loss, ventral edema, muscle fasciculation, mania, recumbency.

**Clinical pathology** Hypertriglyceridemia (triglyceride > 500 mg/dL, 5 mmol/L).

**Necropsy findings** Widespread lipidosis, swollen liver, hepatic rupture.

**ETIOLOGY**

The potentially life-threatening disease hyperlipemia is associated with hyperlipidemia (an abnormal concentration of lipids in blood) in equids. The disease is a result of a derangement in fat metabolism secondary to nutritional stress and, in particular, inadequate energy intake. \(^1\)

Hyperlipemia is the clinical syndrome of depression, weakness, and ventral edema with high blood concentrations of triglycerides and hepatic lipidosis. It carries a high case-fatality rate. A related condition is the detection of hypertriglyceridemia associated with an overt, severe, primary disease (colic, neoplasia, endocrine disease) in which the triglyceridemia likely has minimal clinical importance. Hyperlipemia has its greatest importance as a disease of ponies and donkeys in field situations and related to relatively minor inciting causes.

**EPIDEMIOLOGY**

**Occurrence**

Hyperlipemia occurs worldwide. Although its occurrence is sporadic, multiple cases can occur on a farm when there are a number of at-risk animals exposed to the same inciting factor, such as lack of adequate grazing or supplementary feeding. The annual incidence of the disease in ponies in southeastern Australia is 5%, and it is 2% to 10% in donkeys in the United Kingdom. \(^2\) The case-fatality rate is 40% to 80%, although it appears to be less in hospitalized equids provided more focused care. \(^2,3\) Incidence varies with season and locality; the disease in ponies in Europe occurs most commonly during late gestation (January–March), whereas in southern Australia, the disease is more common in ponies during early lactation (November–January).

**Animal Risk Factors**

Hyperlipemia can occur in any breed of horse or pony and in donkeys, but it is more common in ponies and donkeys. \(^2,3\) Any breed of equid can develop hypertriglyceridemia as a result of a primary disease, but development to the clinical condition lipemia is most common in ponies, miniature horses, miniature donkeys, and donkeys. The disease is considered most common in females, uncommon in pony stallions and geldings, and rare in foals. Most affected ponies are more than 4 years old, and the peak incidence occurs in 9-year-olds. Hypertriglyceridemia occurs in foals secondary to other diseases. \(^2,3\)
Risk factors for hyperlipemia (triglyceride concentration ≥ 4.4 mmol/L) in 449 donkeys with the disease from a population of 3829 donkeys included concurrent disease (odds ratio [OR] 77, 95% confidence interval [CI], 45 to 129), weight loss in previous month (OR = 6.4, 3.6 to 11.3), relocation to a new site (farm) (OR = 3.9, 1.3 to 12), dental disease (OR = 1.7, 1.1 to 2.8), history of inappetence (OR = 3.2, 1.3 to 7.9), and increasing age (OR = 1.26, 1.1 to 1.45).²

Horses and ponies with primary endocrine disease, including pituitary pars intermedia dysfunction (PPID) or suspected diabetes mellitus and conditions associated with insulin resistance, can have marked elevations in serum triglyceride concentrations (10.5 to 60.3 mmol/l) without evident clinical signs attributable to hypertriglyceridemia. The hypertriglyceridemia resolves with successful treatment of the underlying endocrine disease.⁶

Pregnancy and lactation increase the risk of the disease in ponies, but not in donkeys. The disease in miniature horses is always associated with underlying disease, such as colic, which is apparently an important risk factor. Underlying disease is identified in 50% of cases in ponies and 72% of affected donkeys; however, many cases occur in pregnant or lactating pony mares without evidence of other disease.

Overweight ponies and donkeys are at increased risk, and insulin resistance is likely a risk factor for the disease.¹ Onset of disease is often preceded by some sort of stress, typically transport, lactation, food deprivation, or a combination of these factors. Characteristically the disease occurs in fat, middle-aged, pregnant, or lactating ponies that experience a decrease in feed intake. However, the disease is not restricted to this demographic, and horses or thin ponies can develop the disease.

Hypertriglyceridemia is detected in horses with evidence of systemic inflammatory response syndrome (severe illness associated with decreased feed intake). There is no opacity of the plasma or serum, and the hypertriglyceridemia has not been demonstrated to worsen the outcome of the underlying disease.

**PATHOGENESIS**

The combination of the innate insulin resistance of ponies and a nutritional stressor, such as disease, pregnancy, lactation, or food deprivation, results in excessive mobilization of fatty acids from adipose tissue at a rate that exceeds the gluconeogenic and ketogenic capacity of the liver.³ Adipocytes of ponies, in response to norepinephrine, release fatty acids at a rate 6.5 times greater than those of horses, possibly providing at least a partial explanation for the difference in likelihood of differing breeds developing the disease. Lipolysis is mediated by β²-adrenergic receptors in ponies and horses.

The induction of excessive fat mobilization in ponies is likely associated with the well-characterized insulin resistance of this breed, especially in obese individuals. There is no difference between ponies and horses in the extent to which lipolysis is inhibited by insulin. The effect of insulin resistance on glucose uptake from the blood might be exacerbated in sick ponies by the increase in serum cortisol concentrations associated with stress or disease.

Equids have little propensity to produce ketones, and thus the excess fatty acids are reesterified in the liver to triglycerides and released into the circulation as very low-density lipoproteins (VLDLs). The fundamental defect in the disease is in the regulation of free fatty acid release from fat stores as a result of a defect in control of hormone-sensitive lipase, the enzyme responsible for hydrolysis of triglycerides to free fatty acids and glycerol in adipose tissue. Unchecked activity of this enzyme results in mobilization of fatty acids in hyperlipemic ponies that is 40 times the rate in normal ponies. There is no dysfunction of lipoprotein lipase, the enzyme mediating uptake of plasma free fatty acids by extrahepatic tissues, and its activity can be 300% of that of unaffected ponies.

Hyperlipidemia causes widespread lipodisosis and organ dysfunction. Hepatic lipodisosis compromises liver function, resulting in accumulation of toxic metabolites and derangement in coagulation.

**CLINICAL FINDINGS**

The clinical course varies between 3 and 22 days but is generally 6 to 8 days. The unchecked disease progresses from mild depression and inappetence; through profound depression, weakness, and jaundice; to convulsions or acute death in 4 to 7 days. Depression, weight loss, and inappetence are the initial signs in 90% of cases. Approximately 50% of cases have fasciculation of muscles of the limb, trunk, or neck. Ventral edema unrelated to parturition occurs in approximately 50% of cases. Inappetence progresses to anorexia and depression, which is followed by somnolence and hepatic coma. Compulsive walking or mania develops in 30% of cases. Signs of mild colic, including flank watching, stretching, and rolling, are evident in 60% of cases. The incidence of jaundice is variable. Many animals show a willingness to drink, but they are unable to draw water into the mouth and swallow. Others continually lap at water. The temperature is normal or moderately elevated, and heart rate and respiratory rates are increased above normal. Diarrhea is an almost constant feature in the terminal stages.

Visual examination of the plasma or serum phase of a blood sample collected from an affected animal reveals cloudy, milky, mildly opalescent plasma.

**CLINICAL PATHOLOGY**

There is usually leukocytosis with neutrophilia. Hyperlipidemia is a consistent feature of the disease. Serum triglyceride concentrations will be at least 5 mmol/L (500 mg/dL) and can be much higher. Serum cholesterol and free fatty acid concentrations are also increased, although less so than triglycerides. The plasma triglyceride concentration is of minimal prognostic use in ponies, but most American miniature horses with triglyceride concentrations above 1200 mg/dL (12 mmol/L) die.

Plasma glucose concentration is usually low. Ketonemia and ketonuria do not occur. Biochemical evidence of liver disease is characteristic of the advanced disease. Serum activity of gamma-glutamyltransferase (GGT) can be elevated before clinical signs of disease are apparent. Serum creatinine and urea nitrogen concentrations increase as renal function declines. Blood clotting time increases. Metabolic acidosis develops terminally. Hematologic and biochemical variables can also be affected by any underlying disease.

Diagnostic confirmation of hyperlipemia is achieved by demonstration of hyperlipidemia (plasma triglyceride concentrations above 5 mmol/L [500 mg/dL]) in a horse with appropriate clinical signs.

The utility of point-of-care (stall-side) analyzers has been investigated, and both units performed adequately, although not perfectly.⁷ The upper operating range of both units (~6.0 mmol/L) was lower than values for triglycerides in severely affected animals, which limits their usefulness, although it does allow identification of equids with very high concentrations. The instruments have coefficients of variation for measurement of the same sample of 10% to 16%, which limits their usefulness in monitoring responses to treatment. These analyzers are useful for field measurement of triglyceride concentrations in equids, but care should be taken in evaluating values that exceed the range of the instrument.

**Necropsy Findings**

Extensive fatty change is present in most internal organs, but especially in the liver, which is yellow to orange, swollen, and friable. Liver rupture with intraabdominal hemorrhage may be present. Tissue pallor as a result of lipid accumulation is also prominent in the kidney, heart, skeletal muscle, and adrenal cortex. Serosal hemorrhages of the viscera reflect disseminated intravascular coagulation. The necropsy should also include an examination for lesions that might predispose the animal to hyperlipidemia, such as pancreatic damage or laminitis. Histologically, widespread microvascular thrombosis and intracellular lipid in various tissues are evident.
Samples for Postmortem Confirmation of Diagnosis

Samples for postmortem diagnosis include formalin-fixed liver, kidney, heart, adrenal, skeletal muscle, and pancreas for light microscopic examination.

Differential Diagnosis

- Parasitism
- Anemia
- Liver disease, including pyrrolizidine toxicity
- Serum hepatitis
- Affatoxicosis

Hyperlipidemia should be considered in any pony with a history of weight loss, inappetence, and progressive somnolence, especially in late pregnancy or early lactation.

Treatment

- The principles of treatment are as follows:
- Treatment of the underlying or inciting disease
- Restoration and maintenance of a positive energy balance
- Correction of any defects in hydration, acid–base, and electrolyte status
- Reduction of the hyperlipidemia

Every effort should be made to determine whether there is an underlying disease, and if so, it should be treated aggressively. Parasitism is a common inciting disease, as are equine Cushing’s disease and neoplasia (lymphosarcoma, gastric squamous cell carcinoma) in older ponies. The negative energy balance must be corrected. A mature, nonpregnant, and nonlactating 200-kg (440-lb) pony has energy requirements of 9.3 Mcal/d (38 Mj/d), whereas a lactating pony has energy requirements of 13.7 Mcal/d (57.2 Mj/d). Affected animals should be encouraged to eat and must be supplemented either orally or intravenously if they will not eat a sufficient quantity. Supplements, either oral or IV, are unlikely to meet all the animal’s energy requirements, but normalization and stabilization of blood glucose concentrations, and the apparent consequent changes in hormonal milieu, inhibit lipolysis and enhance clearance of triglycerides from plasma and hepatic and renal tissues.

Oral supplementation using commercial equine or human enteral nutrition preparations has been successful for treatment of the disease in American miniature horses and donkeys. If these products are not available, a homemade gruel consisting of alfalfa pellets and cottage cheese can be used. These preparations are administered every 6 hours through a nasogastric tube. Alternatively, glucose can be given orally (1 g/kg, as 5% solution every 6 hours, about 5 L to a 250-kg pony) or intravenously (5% solution, 100 mL/kg per day as a continuous IV infusion). As noted earlier, this dose of glucose will not meet the energy needs of the pony, but it might be sufficient, along with treatment of the underlying disease and supportive care, to restore normal fat metabolism. Provision of parenteral nutrition is feasible and apparently effective, but expensive and technically demanding, thereby restricting its use to veterinary hospitals.\(^\text{10,11}\)

Mares in late pregnancy can be aborted, and lactating mares should have the foal removed.

Dehydration and abnormalities in electrolyte and acid–base status should be corrected by oral or IV administration of isotonic fluids (lactated Ringer’s solution) and, if necessary, sodium bicarbonate.

Encephalopathy associated with liver failure should be treated with oral neomycin (20 mg/kg, every 6 hours) or lactulose (1 mL/kg, every 6 hours).

Hyperlipidemia should be reduced by minimizing free fatty acid production by adipose tissue and enhancing triglyceride removal from plasma. Free fatty acid production is minimized by ensuring adequate energy intake and normal plasma glucose concentrations. Use of insulin and heparin has been recommended for reduction of plasma free fatty acid concentration. However, the efficacy of these treatments is not clear, and the emphasis should be placed on provision of adequate energy intake rather than administration of these hormones. Insulin (protamine zinc insulin) is administered at 0.1 to 0.3 IU/kg SC every 12 to 24 hours. Blood glucose concentrations should be monitored, and the insulin dose may need to be adjusted. Heparin (40 to 100 IU/kg SC every 6 to 12 hours) can be given to increase lipoprotein lipase activity and promote the clearance of triglycerides from plasma. It should be noted that lipoprotein lipase activity is not deficient in affected ponies, and therefore the administration of heparin to ponies with hyperlipemia is not recommended. Severely affected ponies may have an increase in clotting time that could be exacerbated by heparin.

Corticosteroids and adrenocorticotropic hormone are contraindicated in treatment of this disease.

Control

A mature, nonpregnant, and nonlactating 200-kg (440-lb) pony has energy requirements of 9.3 Mcal/d (38 Mj/d), whereas a lactating pony has energy requirements of 13.7 Mcal/d (57.2 Mj/d), and every effort should be made to meet these requirements. This might require dietary supplementation during periods of nutritional stress, such as drought, late pregnancy, peak lactation, or transportation. Ponies should be maintained in optimal body condition, and nutritional stress should be avoided. A parasite and disease control program should be instituted.

Transport of pregnant and lactating ponies should be avoided.

Disorders of Thyroid Function (Hypothyroidism, Hyperthyroidism, Congenital Hypothyroidism, Thyroid Adenoma)

Disorders of thyroid function as a result of abnormalities in the thyroid gland, pituitary gland, or hypothalamus are uncommon in the domestic species and are best documented for the horse. Thyroid disorders secondary to excessive or inadequate intake of iodine or selenium deficiency are discussed under those headings. Animals with low concentrations of thyroid hormones, usually total T3 and total T4, in blood could have nontropical illness syndrome, which is well described in humans and dogs.\(^\text{1}\) Furthermore, neonates have lower concentrations of thyroid hormones in blood than do adults, and premature neonates have even lower concentrations.\(^\text{2}\)

Etiology

Disorders of thyroid function result in hypothyroidism or hyperthyroidism.\(^\text{3}\) Hypothyroidism can result from diseases of the thyroid gland (primary hypothyroidism), pituitary gland (secondary hypothyroidism as a result of reduced secretion of thyroid-stimulating hormone), or hypothalamus (tertiary hypothyroidism, decreased thyrotropin [thyroid-releasing hormone] secretion). Autoimmune thyroiditis has not been described in horses. Lymphocytic thyroiditis occurs in goats. Consumption of propylthiouracil (4 mg/kg body weight orally once daily for 4 to 6 weeks) induces hypothyroidism in adult horses. Administration of trimethoprime-sulfadiazine (30 mg/kg orally q24 h for 8 weeks), which can induce
hypothyroidism in humans and dogs, does not impair thyroid function of most horses. Systemic illness, such as sepsis, or starvation can alter function of the hypothalamic–pituitary–thyroid axis, resulting in euthyroid sick syndrome, more recently termed nonthyroidal illness syndrome. The syndrome has been documented in adult horses and in foals with septic and nonseptic illnesses.2,4,5

**Hereditary congenital hypothyroidism** secondary to defects in thyroglobulin production occurs in sheep, goats, and Afrikaner cattle. The disease is inherited as an autosomal-recessive trait. The cause of congenital hypothyroidism in foals is uncertain, although ingestion of nitrates by the pregnant dam is strongly suspected. Partial thyroidectomy of equine fetuses results in birth of foals with clinical and pathologic characteristics similar to those in the spontaneous disease.

Hyperthyroidism in horses is attributable to functional adenocarcinoma or adenoma of the thyroid gland, but most thyroid tumors are not functional.6,4

**Epidemiology**

The frequency with which hypothyroidism occurs in adult horses is unknown. It is relatively common practice to administer thyroid hormone or iodinated casein to fat horses; to those with laminitis, rhabdomyolysis, or anhidrosis; or to enhance fertility, but documentation of abnormal thyroid function in these animals is rare. None of 79 clinically normal brood mares had an abnormal response to thyroid-stimulating hormone administration, indicating that hypothyroidism is uncommon in this type of animal. Importantly, horses with nonthyroid-related illness often have low concentrations of thyroid hormones in the blood without evidence of thyroid dysfunction—this is referred to as the euthyroid sick or nonthyroidal illness syndrome and is not indicative of thyroid disease.

Abnormalities of the thyroid gland were detected in 12% of 1972 goats examined in India. Of thyroid glands examined from 1000 goats in India, 2.4% had colloid goiter, 39% had parenchymatous goiter, 1.8% had lymphocytic thyroiditis, and 2.1% were fibrotic.

**Congenital hypothyroidism** in foals occurs in western Canada and the western and northern United States. One survey of necropy records of almost 3000 equine fetuses and neonatal foals in western Canada found that 2.7% had histologic evidence of thyroid and musculoskeletal abnormalities consistent with congenital hypothyroidism. Congenital hypothyroidism occurs in Dutch goats, Merino sheep, and Afrikaner cattle. Hypothyroidism is reported in an East Friesian ram.

Hyperthyroidism is a sporadic disease of older horses for which other risk factors are not identified.

Exercise and participation in endurance racing or competitive show jumping usually, but not always, influences serum concentrations of thyroid hormones, but is not considered a pathologic process.9,10 The response depends on the type and intensity of exercise—endurance exercise (40 to 420 km) reduces plasma concentrations of T3 and T4 at the end of the race, with return to basal concentrations by 24 hours.11 Serum T4 concentrations are lower in overtrained or malconditioned young Standardbred horses.12

Thyroid tumors are common in older horses, with ~50% having adenomas evident on histologic examination of the thyroid gland. The clinical course of such tumors is benign, although their size can be quite impressive. Thyroid adenocarcinoma is much less common but has a malignant course.7,8 Fetal undernutrition of lambs during late gestation adversely affects postnatal thyroid function and causes hyperthyroidism as adult sheep.13

**Clinical Findings**

Clinical characteristics of hypothyroidism in adult horses are poorly defined, largely because of the difficulty of confirming the diagnosis and the pharmacologic effect of exogenous thyroid hormones. Clinical abnormalities anecdotally attributed to hypothyroidism include exercise intolerance, infertility, weight gain, malnutrition of body fat, agalactia, anhidrosis, and laminitis, among others. Peripheral neuropathy and keratitis sicca (secondary to facial nerve dysfunction) responsive to levothyroxine administration has been reported in a horse.14 Definitive association of these clinical syndromes with abnormalities of thyroid function is lacking.

Thyroideectomy of horses causes a reduction in resting heart rate and body temperature, docility, decreased food intake, increased cold sensitivity, dull hair coat, and delayed shedding of hair. Blood and plasma volumes of horses increased after removal of the thyroid glands. Effects of thyroideectomy were reversed by administration of thyroxine, with the exception of blood and plasma volume that did not return to euthyroid values. Thyroideectomized horses did not become obese or develop laminitis.

Induced hypothyroidism in goats is evident as a loss of body weight, facial edema, increased cold sensitivity, dull hair coat, and delayed shedding of hair. Blood and plasma volumes of goats increased after removal of the thyroid glands. Effects of thyroideectomy were reversed by administration of thyroxine. Thyroidectomy of equine fetuses results in birth of foals with clinical and pathologic characteristics similar to those in the spontaneous disease.

Horses with hyperthyroidism are tachy-cardic, display cachexia, and have hyperactive behavior. There is usually detectable enlargement of the thyroid gland both on physical examination and on scintigraphic imaging.

Thyroid adenomas are evident as a unilateral nonpalpable enlargement of the thyroid gland of older (>15 years) horses and are detectable on scintigraphic imaging.15 Ultrasonographic and scintigraphic imaging of the thyroid gland of healthy horses is described.16 Thyroid adenocarcinoma presents as metastatic disease with both local and distant spread. Some affected horses have signs of hyperthyroidism, although this is unusual.7

Anhidrosis in horses is not associated with abnormal thyroid function.7

**Clinical Pathology**

Hematologic abnormalities in hypothyroid horses are not well documented. Induced hypothyroidism in horses causes increases in serum concentrations of VLDLs, triglycerides, and cholesterol, and decreased concentrations of NEFAs. Induced hypothyroidism in goats caused hypoglycemia, hypercholesterolemia, and anemia. Hypothyroidism in a ram caused hypercholesterolemia.

**Thyroid Hormone Assays**

Assays are available for measurement of serum concentrations of T3, T4, free T4 (fT4), free T3 (fT3; radioimmunoassay or equilibrium dialysis), and/or TSH in various species.15-20 Values of each of these analytes vary depending on the method of analysis, physiologic status of the animal, and administration of other compounds (Table 17-11). Serum concentrations of thyroid hormones are high at birth and decline with age in ruminants and nonruminants.11,21,22 For example, serum T3 concentrations of weaned Thoroughbred foals declined from 2.89 to 0.29 nmol/L at 7 and 9 months of age, serum T4 concentrations from 100.17 to 21.77 nmol/L at 1 month and at 10 months, serum fT3 concentrations were 6.96 and 1.50 pmol/L at 1 month and 4 months of age, and serum fT4 concentrations were 31.40 and 4.93 pmol/L at 1 month and 9 months of age.13

There are statistically significant diurnal variations in serum concentrations of T3 and T4 in adult horses, with the lowest concentrations observed during the early morning hours, likely coincident with the time at which metabolic rate is lowest (Table 17-8). There is not a seasonal variation in thyroid hormone concentrations in horses.23

**Feed restriction** for 3 to 5 days lowers serum concentrations of T3, T4, and fT4 in horses by 24% to 42%. Administration of phenylbutazone decreases concentrations of fT4 (measured by equilibrium dialysis) and T4 by 4 days of treatment, which can persist for up to 10 days after discontinuation of phenylbutazone. The decrease in T4 is suggested
Table 17-11 Serum or plasma concentrations of thyroid hormones and thyroid-stimulating hormone in foals, horses, donkeys, and cattle

ED, equilibrium dialysis; fT4, free T4; RIA, radioimmunoassay; SD, standard deviation; TSH, thyroid-stimulating hormone; tT3, total T3; tT4, total T4. Mean ± SD or median (95% confidence interval).

To convert µg/dL to nmol/L for T4 or fT4, multiply by 12.87.

To convert ng/dL to nmol/L for fT3 or T3, multiply by 0.0154.

fT4 determined by RIA or ED. PTU, propylthiouracil

to be attributable to displacement of T4 from protein binding sites by phenylbutazone, but this does not explain the decrease in fT4. Topical application twice daily of 50 g of dexamethasone-21-acetate (daily application of 17 mg dexamethasone) suppressed serum T3 and T4 concentrations during 10 days of treatment and for at least 20 days after cessation of treatment. The clinical significance of phenylbutazone-induced decreases in thyroid hormones is uncertain, but should be considered when assessing thyroid function in horses.

Plasma concentrations of fT3, tT3, rT3, fT4, and tT4 of donkeys differs with the age of the donkey and from that of adult horses (Table 17-11). Donkeys less than 5 years of age have higher serum fT3, tT3, rT3, fT4, and tT4 than older donkeys. Because of the number of analytical and physiologic factors that affect serum thyroid hormone concentrations, values considered normal vary considerably, as illustrated by
the finding that 44 of 79 clinically normal nonpregnant broodmares had serum T4 concentrations below the reference range, although responses to TRH were normal. This example illustrates the need to determine reference ranges based on the methodology used and with well-defined definition of the physiologic state of the animals being tested.

Diagnosis of hypothyroidism is aided by demonstration of inappropriate responses of the thyroid gland to administration of TSH or TRH, although the use of these tests depends on determining the increase in serum T3 and/or T4 that is expected in normal horses and in horses with thyroid disease. Of 79 clinically normal mares, all had some increase in T3, and 77 had an increase in T4, 2 hours after IV administration of 1 mg of TRH intravenously. The mean increase in serum T3 concentration was 4.5 times that of resting values (from 0.62 ng/mL to 2.44 ng/mL), whereas serum T4 concentration increased to a mean of 2.1 times that of resting value (from 14.7 ng/mL to 28.6 ng/mL). Although responses to administration of TSH have been reported, responses indicative of abnormal thyroid function—other than complete lack of response—have not been determined, and the utility of the test has been questioned.

The TSH response test involves administration of 5 IU of TSH intravenously. Blood samples are collected before administration and 30 minutes after, 2 hours after, and 4 hours after administration. Serum concentrations of T3 and T4 in healthy horses double after administration of TSH. An alternative involves administration of 5 IU IM and collection of blood before and 3 and 6 hours after TSH administration. TSH is often unavailable.

The TRH response test requires administration of 0.5 to 1 mg of TRH IV. Serum concentrations of T3 and T4 at 2 and 4 hours are double those before TRH administration in horses with normal thyroid function.

Measurement of T4 in serum is useful for assessment of thyroid function. T4 concentration can be normal in horses with low concentrations of T3 and T4, and in this situation is likely indicative of normal thyroid function.

Measurement of serum concentrations of TSH is useful in determining thyroid responsiveness to endogenous TSH. Elevated TSH concentrations in horses with low serum concentrations of T3, T4, or FT4 is indicative of thyroid dysfunction.

Diagnosis of hypothyroidism in horses should be based on the presence of compatible clinical signs, low serum concentrations of thyroid hormones (T3, T4, FT4), elevated concentrations of TSH, lack of an increase in serum concentrations of thyroid hormones in response to administration of TRH, and increased TSH concentration in serum in response to TRH administration. Diagnosis of hypothyroidism should not be based solely on clinical signs or on the measurement of resting (unstimulated) serum T3 or T4 concentrations. At a minimum, appropriate clinical signs and documentation of an abnormal response to stimulation testing (TSH or TRH) are essential for diagnosis of hypothyroidism in horses. Measurements of FT4 concentrations determined by equilibrium dialysis are useful in determining thyroid function in sick horses in which T3 and T4 concentrations are low because FT4 concentrations will be normal in horses without thyroid disease.

Tests with congenital hypothyroidism have abnormally low concentrations of T3 and T4 and less-than-expected increases in serum concentrations of these hormones in response to TSH administration. Horses with hyperthyroidism have markedly elevated concentrations of T3 and T4. Concentrations of T4 do not decline in response to administration of T3. T3 (2.5 mg) is administered intramuscularly twice daily for 3 days and serum concentrations of T3 and T4 measured. T4 concentrations in the serum of healthy horses decline by approximately 80%, whereas those of horses with hyperthyroidism do not decline.

Necropsy findings

Findings on necropsy examination of hypothyroid horses have not been reported. Foals with congenital hypothyroidism have histologic evidence of thyroid hyperplasia, but no gross signs of goiter.

Treatment

Treatment of confirmed hypothyroidism in horses is achieved by administration of levothyroxine (20 μg/kg PO q24h). Serum T3 concentrations peak in 1 hour and then decline, whereas concentrations of T4 peak in 2 hours and persist for 24 hours. Administration of levothyroxine to healthy ( euthyroid) horses resulted in 3.7- to 5.4-fold increases in pretreatment total T4 concentrations in serum. The clinical status of horses treated for hypothyroidism should be monitored during treatment and serum concentrations of T3 and T4 measured every several months. Iodinated casein, which is no longer readily available in the United States, is administered at 5 g/450 kg body weight orally once daily. Administration of thyroxine or iodinated casein for treatment of low serum thyroid hormone concentrations in horses with nonthyroidal illness syndrome ( euthyroid sick syndrome) should be done judiciously, if at all.

A response to thyroxine administration is not necessarily confirmation of hypothyroidism because thyroxine can have marked effects in horses with normal thyroid function. Administration of thyroxine (up to 96 mg/470 kg horse, orally once daily) increases serum concentrations of T4 and, to a lesser extent, FT4, and decreases concentrations of TSH. The increases in T4 are associated with a loss of body weight; decreases in serum concentrations of triglycerides, cholesterol, and VLDLs; and an increase in whole-body insulin sensitivity. Thyroxine should be administered with caution to horses with normal thyroid function.

Control

There are no recognized control measures for hypothyroidism in adult horses. Minimizing intake of nitrates by pregnant mares appears warranted, but definitive proof of the efficacy of this practice is lacking. Pregnant mares should not be fed fodder or supplements that interfere with thyroid function.

The inherited disorder in sheep, cattle, and goats can be prevented by selective breeding.

Iodine deficiency

Synopsis

Etiology Primary dietary deficiency of iodine or secondary to conditioning factors such as calcium, Brassica plants, or bacterial pollution of water.

Epidemiology In all species, most common in continental landmasses. Neonatal animals. Diets of dams deficient in iodine as a result of
of abundant pasture growth or leaching of iodine from soil in years of unusually high rainfall, or diets containing conditioning factors such as certain plants.

**Signs** Goiter as palpable enlargement of thyroid gland. Neonatal mortality as a result of stillbirths or weak neonates not able to suck that die in few days, alopecia at birth, myxedema.

**Clinical pathology** Serum total iodine concentration.

**Necropsy findings** Thyroid enlargement, alopecia, myxedema.

**Diagnostic confirmation** Goiter and iodine deficiency.

**Differential diagnosis list**
- Weak-calf syndrome
- Abortion
- Congenital defects
- Hypothyroidism

**Treatment** During an outbreak, oral administration of 280 mg/head potassium iodide to pregnant ewes and provision of iodized salt licks. Lambs with goiter can be administered 20 mg potassium iodide per os, once.

**Control** Ensure adequate dietary intake of iodine in pregnant animals.

Iodine metabolism is influenced by physiologic and environmental factors, making assessment of thyroid status, and the need for supplementation, challenging. See previous section for a discussion of hypothyroidism.

**ETIOLOGY**

Iodine deficiency can be a result of deficient iodine intake or secondarily conditioned by a high intake of calcium, diets consisting largely of *Brassica* spp., or gross bacterial pollution of feedstuffs or drinking water. A continued intake of a low level of cyanogenetic glycosides (e.g., in white clover) is commonly associated with a high incidence of goitrous offspring. Linamarin, a glycoside in linseed meal, is the agent producing goiter in newborn lambs born from ewes fed the meal during pregnancy. A continued intake of the grass *Cynodon aethiopicus*, which has low-iodine and high–cyanogenetic glucoside content, can cause goiter in lambs. Rapseed and rapseed meal are also goitrogenic. Presence of abundant pasture after unusually high rainfall and a “seasonal break” (marked increase in pasture growth in the weeks after end of summer) is associated with clinical iodine deficiency in newborn lambs.  

Goiter or hypothyroidism in newborn lambs occurs when pregnant ewes have a low iodine intake or ingest goitrogens.

**EPIDEMIOLOGY**

**Occurrence**

Goiter caused by iodine deficiency occurs in all of the continental landmasses. It is not of major economic importance because of the ease of recognition and correction, but if neglected it can cause heavy mortalities in newborn animals. Stillbirth or death of newborn lambs reduced a pregnancy rate at midterm (number of fetuses detected by ultrasonographic examination/number of ewes) of 130% to a marking rate of ~2 weeks of age to 70%. The most common cause of iodine deficiency in farm animals is the failure to provide iodine in the diet. The sporadic occurrence of the disease in marginal areas attracts most attention. An epidemiologic survey in Germany found that up to 10% of cattle and sheep farms and 15% of swine herds were affected with iodine deficiency, which included both primary and secondary conditions as a result of the presence of nitrates, thiocyanates, or glucosinolates in the diet.

The importance of subclinical iodine deficiency as a cause of neonatal mortality could be much greater than that of clinical disease. For example, in southern Australia, ewes supplemented with iodine by a single injection of iodine in oil have shown lower mortality in the lambs, have grown larger lambs, or performed the same as controls. In New Zealand, subclinical iodine deficiency has been recognized in a sheep flock in which fertility and lamb perinatal mortality occurred and was corrected by supplementation of the ewes with iodine. The annual cost associated with iodine deficiency in one Manawata Romney flock was conservatively estimated at $6.00 per ewe. Iodine supplementation reduces perinatal mortality and increases lambing percentage by 14% to 21% in pasture-fed ewes. Thus subclinical iodine deficiency can affect reproductive performance and perinatal lamb mortality.

Young animals are more likely to bear goitrous offspring than older ones, and this may account for the apparent breed susceptibility of Dorset Horn sheep, which mate at an earlier age than other breeds.

A survey of crossbred cows in the Punjab of India found that 36% of cows were iodine deficient, with considerable geographic variation from 0% to 86% within Punjab. The cardinal clinical signs of iodine deficiency were absent, and basal plasma T3 (triiodothyronine) and T4 (plasma thyroxine) concentrations and their ratios did not differ between deficient and control cows. The response to injection of 1 mL of 78% ethiodized oil can prevent the deficiency for more than 70 days.

**Risk Factors**

**Dietary and Environmental Factors**

A simple deficiency of iodine in the diet and drinking water can occur and is related to geographic circumstances. Areas where the soil iodine is not replenished by cyclical accessions of oceanic iodine include large continental landmasses and coastal areas where prevailing winds are offshore. In such areas, iodine deficiency is most likely to occur where rainfall is heavy and soil iodine is continually depleted by leaching. Iodine ingested in the diet comes largely from ingestion of soil, either directly or on pasture. Consequently, abundant pasture growth can reduce intake of soil and lead to iodine deficiency in sheep.

Soil formations rich in calcium or lacking in humus are also likely to be relatively deficient in iodine. The ability of soils to retain iodine under conditions of heavy rainfall is directly related to their humus content, and limestone soils are, in general, low in organic matter. A high dietary intake of calcium also decreases intestinal absorption of iodine, and in some areas, heavy applications of lime to pasture are followed by the development of goiter in lambs. This factor can also be important in areas where drinking water is heavily mineralized.

There are several situations in which the relationship between iodine intake and the occurrence of goiter is not readily apparent. Goiter may occur on pastures containing adequate iodine; it is then usually ascribed to a secondary or conditioned iodine deficiency. A diet rich in plants of the *Brassica* spp., including cabbages and brussels sprouts, may cause simple goiter and hypothyroidism in rabbits, which is preventable by administering iodine. Severe iodine deficiency can occur when ewes are fed *Brassica* crops for long periods. Brassicas such as swedes, turnips, and kale have low iodine content and contain goitrogens, and they may result in weak newborn lambs with enlarged thyroid glands. Goiter occurred in 85% of lambs examined at necropsy that born from ewes fed on the *Brassica* crop and not supplemented with iodine.

Diffuse hyperplastic goiter has occurred in calves in beef cows in Japan that were on pasture or being fed feed containing *Rorippa indica*, Hiern, genus *Brassica*, family Crucifera, Inagurash, which contains thiocyanate. The iodine content of the waters on affected farms was low at 0.361 µg/L and 0.811 µg/L and that of the pastures, 87 µg/kg and 121 µg/kg, on two different farms.

Hypothyroidism has also been produced in rats by feeding rapseed and in mice by feeding rapseed oil meal. Feeding large quantities of kale to pregnant ewes causes a high incidence of goiter and hypothyroidism, also preventable by administering iodine in the newborn lambs. The goitrogenic substance in these plants is probably a glucosinolate capable of producing thiocyanate in the rumen. The thiocyanate content, or potential content, varies between varieties of kale, being much less in rape-kale, which also does not show the twofold increase in thiocyanate content other varieties show in autumn. Small young leaves contain up to five times as much thiocyanate as large, fully formed leaves. Some of these plants are excellent sources of feed, and in some areas, it is...
probably economical to continue feeding them, provided suitable measures are taken to prevent goiter in the newborn. Although kale also causes mild goiter in weaned lambs, this does not appear to reduce their rate of gain.

A diet high in linseed meal (20% of ration) given to pregnant ewes may result in a high incidence of goitrous lambs, which is preventable with iodine or thyroxine. Under experimental conditions, groundnuts are goitrogenic for rats, the goitrogenic substance being a glycoside-arachisodiose. The goitrogenic effect is inhibited by supplementation of the diet with small amounts of iodine. Soybean by-products are also considered to be goitrogenic. Gross bacterial contamination of drinking water by sewage is a cause of goiter in humans in countries where hygiene is poor. There is a record of a severe outbreak of goitrous calves from cattle running on pasture heavily dressed with crude sewage. Prophylactic dosing of the cows with potassium iodide prevented further cases. Feeding sewage sludge is also linked to the occurrence of goiter.

Goiter in lambs may occur when permanent pasture is plowed and re-sown. This may be a result of the sudden loss of decomposition and leaching of iodine-binding humus in soils of marginal iodine content. In subsequent years the disease may not appear. There may be some relation between this occurrence of goiter and the known variation in the iodine content of particular plant species, especially if new pasture species are sown when the pasture is plowed. The maximum iodine content of some plants is controlled by a strongly inherited factor and is independent of soil type or season. Thus in the same pasture, perennial ryegrass may contain 146 µg iodine per 100 g dry matter (DM) and Yorkshire grass only 7 µg/100 g DM. Because goiter has occurred in lambs when the ewes are on a diet containing less than 30 µg iodine per 100 g DM, the importance of particular plant species becomes apparent. A high incidence of goiter associated with heavy mortality has been observed in the newborn lambs of ewes grazing on pasture dominated by white clover and by subterranean clover and perennial ryegrass.

Thyroid-weight: birth-weight ratios greater than 0.8 g/kg in lambs are indicative of iodine deficiency and should be considered a risk factor for iodine deficiency in lambs. Ratios less than 0.4 g/kg rarely occur among deficient flocks.

Congenital goiter has been observed in foals born to mares on low iodine intake, but also to mares fed an excessive amount of iodine during pregnancy.

**PATHOGENESIS**

Iodine deficiency results in a decreased production of thyroxine and stimulation of the secretion of thyrotropic hormone by the pituitary gland. This commonly results in hyperplasia of thyroid tissue and a considerable enlargement of the gland. Most cases of goiter of the newborn are of this type. The primary deficiency of thyroxine is responsible for the weakly developed and hair abnormality of the affected animals. Although the defect is described as hairlessness, it is truly hypoplasia of the hairs, with many very slender hairs present and a concurrent absence and diminution in the size of hair follicles. A hyperplastic goiter is highly vascular, and the gland can be felt to pulsate with the arterial pulse; a loud murmur may be audible over the gland. Colloid goiter is less common in animals and probably represents an involitional stage after primary hyperplasia.

Other factors, particularly the ingestion of low levels of cyanide, exert their effects by inhibiting the metabolic activity of the thyroid epithelium and restricting the uptake of iodide. Thiocyanates and sulfocyanates are formed during the process of detoxication of cyanide in the liver, and these substances have a pronounced depressive effect on iodine uptake by the thyroid. Some pasture and fodder plants, including white clover, rape, and kale, are known to have a moderate content of cyanogenetic glucosides. These goitrogenic substances may appear in the milk and provide a toxic hazard to both animals and humans. The inherited form in cattle is a result of the increased activity of an enzyme that deiodinates iodotyrosines so rapidly that the formation of thyroxine is inhibited.

Iodine is an essential element for normal fetal brain and physical development in sheep. A severe iodine deficiency in pregnant ewes causes reduction in fetal brain and body weight from 70 days of gestation to parturition. The effects are mediated by a combination of maternal and fetal hypothyroidism, the effect of maternal hypothyroidism being earlier than the onset of fetal thyroid secretion. There is also evidence of fetal hypothyroidisms and absence of wool growth and delayed skeletal maturation near parturition.

**CLINICAL FINDINGS**

Goiter is an unambiguous indicator of iodine deficiency in lambs and calves, but clinically important increases in thyroid size might be easily missed unless careful attention is paid to assessment of the thyroid gland in newborns. Thyroid volume can be estimated in calves by ultrasonographic examination. It is important to recognize that ingestion of excessive iodine also can result in goiter in neonates and adults.

A high incidence of stillbirths and weak, newborn animals is the most common manifestation of iodine deficiency. Partial or complete alopecia and palpable enlargement of the thyroid gland are other signs that occur with varying frequency in the different species. Affected foals have a normal hair coat and little thyroid enlargement, but they are very weak at birth. In most cases, they are unable to stand without support, and many are too weak to suck. Excessive flexion of the lower forelegs and extension of lower parts of the hindlegs has also been observed in affected foals. Defective ossification occurs in foals and lambs (Fig. 17-8), and in foals the manifestation is collapse of the central and third tarsal bones, leading to lameness and deformity of the hock. Enlargement of the thyroid also occurs commonly in adult horses in affected areas, with Thoroughbreds and light horses being more susceptible than draft animals.

In cattle, the incidence of thyroid enlargement in adults is much lower than in horses, and the cardinal manifestations are gross enlargement of the thyroid gland and weakness in newborn calves. If they are assisted to suck for a few days, recovery is usual, but if they are born on the range during inclement weather, many will die. In some instances, the thyroid gland is sufficiently large to cause obstruction to respiration. Affected calves have a thick neck and appear to be suffocating. Lethargy, weakness, and difficulty in consuming colostrum are common. Partial alopecia is a rare accompaniment.

In pigs, the characteristic findings are birth of hairless, stillborn, or weak piglets, often with myxedema of the skin of the neck. The hairlessness is most marked on the limbs. Most affected piglets die within a few hours of birth. Thyroid enlargement may be present, but it is never sufficiently great to cause visible swelling in the live pig. Survivors are lethargic, do not grow well, and have a waddling gait and leg weaknesses as a result of weakness of ligaments and joints.

Adult sheep in iodine-deficient areas can show a high incidence of thyroid enlargement, but are clinically normal in other respects. Newborn lambs manifest weakness, extensive alopecia, and palpable, if not visible, enlargement of the thyroid glands (Fig. 17-9). The gestation length of ewes may be increased, and there is increased perinatal mortality, especially in inclement weather. Marginal iodine deficiency can result in nonspecific production losses from embryonic mortality or high perinatal lamb death and reduced lamb growth rates and is difficult to diagnose.

Goats present a similar clinical picture, except that all abnormalities are more severe than in lambs. Goat kids are goitrous and alopecic. The degree of alopecia varies from complete absence of hair, through very fine hair, to hair that is almost normal.

Animals surviving the initial danger period after birth may recover, except for partial persistence of the goiter. The glands may pulsate with the normal arterial pulse and may extend down a greater part of the neck and cause some local edema. Auscultation and palpation of the jugular furrow may reveal the presence of a murmur and thrill,
the “thyroid thrill,” as a result of the increased arterial blood supply of the glands. Calves that had larger goiter and were hairless (n = 8) died within the first day of life, whereas four others with moderate goiter and normal hair lived.5

Although loss of condition, decreased milk production, and weakness might be anticipated, these signs are not usually observed in adults. Loss of libido in the bull, failure to express estrus in the cow, and a high incidence of aborted, stillborn, or weak calves have been suggested as manifestations of hypothyroidism in cattle, whereas prolonged gestation is reported in mares, ewes, and sows. As noted previously, pathognomonic changes in production indices are not available for diagnosis of iodine deficiency.2

Goiter has occurred in newborn foals whose mares were supplemented with excess iodine during the last 24 hours of pregnancy.

**CLINICAL PATHOLOGY**

There are no wholly satisfactory indices of the severity of iodine deficiency, and biochemical markers of iodine metabolism, such as serum iodine or thyroxine (T4) and triiodothyronine (T3) concentrations, have not been shown to accurately and reliably reflect an animal’s iodine status, identify marginal deficiency, or predict the production response of a flock to iodine supplementation.7 Thyroid-related hormones often do not discriminate between adequate and marginal iodine status in pasture-fed livestock during supplementation trials, probably a result of the complex, adaptive systems maintaining homeostasis of these important regulators of cell growth and metabolic rate.7 Knowles and Grace (2007) think that data are inadequate to quantify the relationship between iodine status and an economically relevant measure of animal performance, and this has hindered the setting of laboratory reference ranges for biomarkers.7

However, measurement of serum total iodine concentration, which is an elemental determination that comprises the iodinated hormones plus various chemical forms of serum inorganic iodine, might be more effective in diagnosing iodine deficiency than measurement of serum iodine concentration or biochemical markers (see following “Control” section).7

Several criteria have been used for the laboratory diagnosis of iodine deficiency in sheep, including T3 and T4 and related hormones. They include thyroid weight, lamb thyroid-to-body-weight ratio, and comparison of serum T4 (serum thyroxine) concentrations in lamb and dam. However, concentrations of biochemical and hormonal markers are variable and difficult to compare among reports because of, among other factors, differing assay methodologies.8 Measurement of thyroid-stimulating hormone concentrations (TSH, thyrotropin) appears to be useful in detection of hypothyroidism attributed to iodine deficiency in calves.4 TSH is significantly higher in goats than calves with healthy calves, whereas plasma iodine concentrations do not differ. Concentrations, and ratios, of T4, T4/T3 ratio, T4/TSH ratio, rT3, and T3 are higher in healthy calves than in calves with goiter. Calves with goiter that die have higher TSH values; lower T4, T3, T4/TSH, and rT3; but similar T4/T3 ratio (P > 0.1) than calves with goiter that live. In the absence of TSH assay, the T4/T3 ratio can be used to diagnose hypothyroidism in newborn calves.4 Feed iodine concentration was 175 mg/kg DM (reference range > 1200 mg/kg DM) in a herd of cattle with 10% incidence of stillbirth and death of newborns as a result of iodine deficiency.4

Thyroid-weight:birth-weight ratios greater than 0.8 g/kg in newborn lambs are indicative of iodine deficiency. Ratios less than 0.4 g/kg rarely occur in lambs of flocks deficient in iodine. Intermediate ratios are ambiguous.2 The relationship between thyroid and body weight is not linear and is best defined by a probit plot (Fig. 17-10), and this nonlinear relationship should be considered when interpreting these ratios for diagnosis of iodine deficiency and need for supplementation.7

Other tests are concentrations of iodine in plasma, milk, and urine, all of which reflect current iodine status rather than revealing a profile or providing indications of previous iodine status. Estimations of iodine levels in the blood and milk are reliable indicators of the iodine status of the animal. There may be between-breed differences in blood iodine levels, but levels of 2.4 to 14 µg of protein-bound iodine per 100 mL of plasma appear to be in the normal range. In ewes, an iodine concentration in milk of below 8 µg/L indicates a state of iodine deficiency. Bulk-tank milk iodine content should be greater than 300 µg/L.
Changes in serum thyroid hormone levels in newborn calves have been used as a diagnostic index in endemic goiter, but their high variation has been unreliable. The T4/T3 ratio of calves with goiter was lower than in healthy calves and adult cows, and it may be a useful diagnostic aid.

In determining the iodine status of an area, iodine levels in soil and pasture should be obtained, but the relationship between these levels, and between them and the status of the grazing animal, may be complicated by conditioning factors.

**NECROPSY FINDINGS**

Macroscopic thyroid enlargement, alopecia, and myxedema may be evident. The weights of thyroid glands have diagnostic value. In full-term normal calves the average fresh weight is 6.5 g; in lambs 2 g is average. Newborn lambs from ewes unsupplemented with iodine had a mean ratio of thyroid weight (g) to body weight (kg) of 0.40 g/kg or greater. In calves with severe thyroid hyperplasia, the gland may be heavier than 20 g.

The iodine content of the thyroid will also give some indication of the iodine status of the animal. At birth, a level of 0.03% of iodine on a wet-weight basis (0.1% on dry weight) can be considered to be the critical level in cattle and sheep. On histologic examination, hyperplasia of the glandular epithelium may be seen. Follicles depleted of colloid, infolded, and lined by columnar epithelium are indicative of hypothyroidism in lambs born from ewes unsupplemented with iodine.

The hair follicles will be found to be hypoplastic. Delayed osseous maturation, manifested by absence of centers of ossification, is also apparent in goitrous newborn lambs.

**TREATMENT**

When outbreaks of iodine deficiency occur in neonates, the emphasis is usually on providing additional iodine to the pregnant dams. The recommendations for control can be adapted to the treatment of affected animals. During an outbreak, oral administration of 280 mg/head potassium iodide to pregnant ewes and provision of iodized salt licks is advisable. Lambs with goiter can be administered 20 mg potassium iodide per os, once.

**CONTROL**

The recommended dietary intake of iodine for cattle is 0.8 to 1.2 mg/kg DM of feed for lactating and pregnant cows and 0.1 to 0.3 mg/kg DM of feed for nonpregnant cows and calves. Monitoring of lamb thyroid: body-weight ratios in areas at risk for iodine deficiency can be useful in determining the need for supplementation before and/or during pregnancy. Thyroid-weight:birth-weight ratios greater than 0.8 g/kg are indicative of iodine deficiency, and ewes should be supplemented premating or during pregnancy to prevent goiter the following year. Ratios less than 0.4 g/kg rarely occurred among deficient flocks, so the probability of benefit from supplementation is low. Intermediate ratios are ambiguous, and individual-farm supplementation trials might be required to detect and manage the risks of marginal deficiency.

Pastures in New Zealand that contain 0.24 mg iodine/kg DM provide an adequate intake for dairy cows. The injection of iodine (iodized oil) IM three times at a dose of 2370 mg iodine/dose at the start of lactation and at 100-day intervals increased iodine concentrations in milk to 58 µg/L for at least 98 days after each treatment. Two iodine injections at 100-day intervals increased milk iodine concentrations to 160 µg/L and 211 µg/L at least 55 days after each treatment, but had no effect on serum thyroid hormone concentrations. Iodine supplementation had no effect on milk, milk fat, or milk protein yield. Increasing iodine concentration in milk by IM injection of iodine could provide a method for increasing iodine intakes of humans, especially children.

Iodine can be provided in salt or a mineral mixture. The loss of iodine from salt blocks may be appreciable, and an iodine preparation that is stable but contains sufficient available iodine is required. Potassium iodate satisfies these requirements and should be provided as 200 mg of potassium iodate per kilogram of salt. Potassium iodide alone is unsuitable, but when mixed with calcium stearate (8% of the stearate in potassium iodide) it is suitable for addition to salt—200 mg/kg of salt.

Individual dosing of pregnant ewes, on two occasions during the fourth and fifth months of pregnancy, with 280 mg potassium iodide or 370 mg potassium iodate has been found to be effective in the prevention of goiter in lambs when the ewes are on a heavy diet of kale. For individual animals, weekly application of tincture of iodine (1 mL given IM 10 days after each treatment) has been found to be effective in the prevention of goiter in lambs when the ewes are on a heavy diet of kale. For individual animals, weekly application of tincture of iodine (4 mL for cattle; 2 mL for pigs and sheep) to the inside of the flank is also an effective preventive. The iodine can also be administered as an injection in poppy seed oil (containing 40% bound iodine): 1 mL given IM 7 to 9 weeks before lambing is sufficient to prevent severe goiter and neonatal mortality in the lambs. Control of goiter can be achieved for up to 2 years. The gestation period is also

**Fig. 17-10 Plot of probability that a flock of ewes will respond to iodine supplementation based on lamb thyroid-weight:body-weight ratios. A ratio of 0.40 g/kg (95% confidence interval [Cl] = 0.29 to 0.47) predicted with 35% probability, and a ratio of 0.80 g/kg (95% CI = 0.70 to 0.99) predicted with 90% probability, that a lamb came from an unsupplemented (i.e., iodine-deficient) flock. (Reproduced with permission from Knowles SO, et al. *N Z Vet J.* 2007;55:314.)"
supplementation in sheep is as follows:2

to ewes during late pregnancy. Venting congenital goiter in lambs when fed milk concentrations of lactation were not affected.10

centrations in lambs born of ewes that were supplemented for 161 days. 2 Milk concentrations of lactation were not affected.10

centrations from 60.1 µg/L (n = 20; p < 0.001) at lambing ~99 days later, regardless of forage fed. High serum iodine concentrations persisted for 127 to 206 days after supplementation.7 Diet did not affect iodine concentrations in ewe serum or milk. Responses of serum total iodine concentration (an elemental determination that comprises the iodinated hormones plus various chemical forms of serum inorganic iodine1) to injection of iodized oil to sheep are proportional to dose level increasing from 42 µg/L to approximately 150 and 240 µg/L for sheep administered either 300 mg or 400 mg of iodine, remaining elevated for 161 days.7 Milk concentrations of iodine were 26, 271, and 425 µg/L for sheep administered no supplemental iodine or 300 mg or 400 mg, respectively. Mean serum iodine concentrations of lambs from supplemented ewes with 300 mg or 400 mg iodine were 237 and 287 µg I/L at birth, and by weaning were similar (62 ± 3 µg/L). Concentrations in lambs born of ewes that were not supplemented were less than ~140 µg/L and were markedly affected by the diet of the ewe.10

Administration of 0.45 mg or 0.90 mg of potassium iodide orally daily to crossbred dairy goats increased mean milk iodine concentrations from 60.1 ± 50.5 (unsupplemented goats) to 78.8 ± 55.4 and 130.2 ± 62.0 µg/L (mean ± SD), respectively. Milk production was not affected.10

A device to release iodine slowly into the forestomachs, while still retaining its position there, has given good results in preventing congenital goiter in lambs when fed to ewes during late pregnancy. A recommended approach for iodine supplementation in sheep is as follows:7

1. If feeding Brassica crops, then supplement ewes.

2. If any lamb thyroid-weight : birth-weight ratio is greater than 0.8 g/kg, then supplement ewes. The relationship between thyroid weight and body weight is not linear and is best defined by a probit plot (Fig. 17-10), and this nonlinear relationship should be considered when interpreting these ratios for diagnosis of iodine deficiency and need for supplementation.7

3. If all or most thyroid-weight : birth-weight ratios are less than 0.4 g/kg, there is probably no need to supplement ewes because the probability of benefit is low.

4. If many thyroid-weight : birth-weight ratios fall between 0.4 and 0.8 g/kg, then the iodine status of the flock is unclear and can be impossible to determine from biomarkers. Supplement the ewes if other evidence is persuasive, such as occurrence of iodine deficiency in the district. An on-farm supplementation trial might be required to detect marginal deficiency on these properties.

INHERITED GOITER

Inherited goiter is recorded in Merino sheep, Afrikaner cattle, crossbred Sanen dwarf goats, Boer goats, possibly Poll Dorset sheep, and pigs, and it appears to be inherited as a recessive character. The essential defect is in the synthesis of abnormal thyroid hormone, leading to increased production of thyrotropic factor in the pituitary gland, causing in turn a hyperplasia of the thyroid gland. In Afrikaner cattle the defect stems from an abnormality of the basic RNA, and heterozygotes can be identified by blot hybridization analysis. Clinically in sheep, there is a high level of mortality, enlargement of the thyroid above the normal 2.8 g (but varying greatly up to 222 g), and the appearance of lustrous or silky wool in the fleeces of some lambs. Other defects that occur concurrently are edema and floppiness of ears, enlargement and outward or inward bowing of the front legs at the knees, and dorsoventral flattening of the nasal area. The thyroglobulin deficiency in the neonatal lamb may result in defective fetal lung development and the appearance of neonatal respiratory distress syndrome; there is dyspnea at birth. The clinical picture in goats is the same as for lambs. It includes retardation of growth, sluggish behavior, rough and sparse hair coat that worsens as the goats get older, and thick and scaly skin.

In Afrikaner cattle, most of the losses are from stillbirths or from early neonatal deaths. Some are caused by tracheal compression from the enlarged gland. It is the calves with the largest glands that have the greatest mortality. In these cattle there may be a concurrent inherited gray coat color, a defect in a red breed. In pigs, hairless and swollen piglets with enlarged thyroid glands occur, in the proportions with normal piglets consistent with an autosomal-recessive mode of inheritance.

Diseases Caused by Nutritional Deficiencies

INTRODUCTION

Three criteria are suggested for the assessment of the importance of nutrition in the etiology of a disease state in a single animal or in a group of animals:

- Is there evidence from an examination of the diet that a deficiency of a specific nutrient or nutrients may be occurring?

- Is there evidence from an examination of the animals that a deficiency of the suspected essential nutrient or nutrients could cause the observed disease?

- Does supplementation of the diet with the essential nutrient or nutrients prevent or cure the condition?

The difficulties encountered in satisfying these criteria, and making an accurate and reliable diagnosis of a nutritional deficiency, increase as investigations progress into the area of trace element and vitamin nutrition. The concentration of these micronutrients in feedstuffs and body tissues are exceedingly small, and assays are often difficult and expensive. Because of these difficulties it is becoming more acceptable to describe individual syndromes as “responsive diseases”—that is, the investigation satisfies only the third of the previously listed three criteria. This practice is not ideal, but has advantages in that it is more a more cost-effective approach, and relevant control measures are directly assessed.

EVIDENCE OF A DEFICIENCY AS THE CAUSE OF THE DISEASE

Evidence of a deficiency as the cause of the disease will include evidence of a deficiency in the diet or an abnormal absorption, utilization, or requirement of the nutrient under consideration. Additional evidence may be obtained by chemical or biological examination of the feed.

Diet

The diet for a considerable period before the occurrence of the disease must be considered because body stores of most dietary factors may delay the appearance of clinical signs. Specific deficiencies are likely to be associated with particular soil types, and in many instances national or local soil and geological maps may predict the likely occurrence of a nutritional disease. Diseases of plants may also indicate specific soil deficiencies, such as “reclamation disease” of oats, which indicates copper deficiency. The predominant
Abnormal Absorption

Although a diet may contain adequate amounts of a particular nutrient, some other factor, by decreasing its absorption, may induce a deficiency. For example, excess phosphate reduces calcium absorption, excess calcium reduces the absorption of iodine, and the absence of bile salts prevents proper absorption of the fat-soluble vitamins. Chronic enteritis reduces the absorption of most essential nutrients. The list of antagonisms that exist between elements continues to grow, most being an interference with absorption. For example, excess calcium in the diet interferes with the absorption of fluorine, lead, zinc, and cadmium, such that it may cause nutritional deficiencies of these elements, but it also reduces their toxic effects when they are present in the diet in excessive amounts.

Abnormal Utilization of Ingested Nutrients

Abnormal utilization of ingested nutrients may also have an effect on the development of conditioned deficiency diseases. For example, molybdenum and sulfate reduce copper storage, vitamin E has a sparing effect on vitamin A, and thiamine reduces the dietary requirement for essential fatty acids.

Abnormal Requirement

An enhanced growth rate of animals, either by improved nutrition or genetic selection, may increase their requirement for specific nutrients to the point where deficiency disease occurs. There seems to be little doubt that there is a genetic variation in mineral metabolism, and it has been suggested that it may be possible to breed sheep to "fit" deficiency conditions. The significance of the inherited component of an animal's nutritional requirement is unknown, but should not be overlooked when policies to upgrade livestock in deficient areas are being planned.

Evidence of a Deficiency Associated with the Disease

Evidence of a deficiency associated with the disease is usually available from experimental work that demonstrates the clinical signs and necropsy findings produced by each deficiency. Several modifying factors may confuse the issue. Under natural circumstances, nutritional deficiencies may not be a single entity, and thus clinical and necropsy findings will often be complicated by deficiencies of other factors and intercurrent infections. Most syndromes are variable and insidious in their onset, and clinical signs and gross necropsy lesions in many nutritional deficiency diseases are either minimal or nonspecific. This increases the challenge of making a definitive diagnosis.

Consequently, laboratory examination of blood and animal tissues is an essential diagnostic aid in many instances. However, the normal range of blood or tissue concentrations of minerals and vitamins, or their biochemical markers, and those values that indicate deficiency, are often not well established. Experimentally induced and naturally occurring nutritional deficiencies provide an indication of the changes that occur in the concentrations of a particular nutrient, but variations resulting from age, genotype, production cycle, length of time on the inadequate diet, previous body stores of the element, and intercurrent disease and stressors can complicate the results, making them difficult to interpret.

In most cases, nutritional deficiencies affect a proportion of the herd or the flock at the same time. The clinicopathological examination should include a selection of both normal and clinically affected animals because the comparison of results from these groups allows a more accurate and reliable interpretation of laboratory tests, facilitating a diagnosis.

Evidence Based on Cure or Prevention by Correction of the Deficiency

The best test of the diagnosis of a suspected nutritional deficiency is to observe the effect of supplementing that nutrient, either directly to the animal or via the ration. Con founding factors can occur, such as spontaneous recovery; hence, adequate controls and a sufficient sample size are essential. Curative responses may be poor because of an inadequate dose or advanced tissue damage. Alternatively, the abnormality may have only been a predisposing or secondary factor to another factor that is still present. A common cause of confounding in therapeutic trials is the impurity or bioactivity of the preparations used, particularly with trace elements and vitamins. The preparations used may also have some intrinsic pharmacologic activity and hence partially or temporarily ameliorate the condition without a deficiency actually having been present.

Monitoring of Nutritional Status

On breeding farms, there are several different age groups of animals at different levels of growth and production. This requires close surveillance to avoid either a deficiency or overnutrition in each class of animal. Scoring of the body condition of dairy and beef cattle, sheep, and pigs is commonly used as an indicator of the adequacy of the diet leading to the present time (termed prior nutrition). The feeds and feeding program have a major influence on reproductive performance, and hence growth and milk production and must be monitored regularly. The veterinarian must be aware of any changes in the feeding program that have occurred since the last farm visit or that are intended in the near future. Veterinary clinical nutrition is now a specialty that should provide new and useful information for the practitioner working with a particular species or class of food animals. An experienced and competent nutritionist should be consulted to assist with complex nutritional problems.

Nutritional Management in Dairy Herds

Advising farms about nutrition is a key activity for dairy cattle practitioners. Feed costs are approximately 60% of the total cost of producing milk, so even minor improvements in feeding efficiency can be profitable.

Some dairy practitioners function as the nutritional specialist for the dairy farms they serve, collecting feed samples for nutrient analysis, formulating rations, and advising on crop and harvesting conditions. These veterinarians often devote a considerable amount of their professional time to nutritional management. Nevertheless, it is common for farms to employ a professional nutritionist or to use a nutritionist employed by a feed company or local cooperative. These professionals generally formulate the rations and submit feed samples for nutrient analysis. For these herds, the veterinarian can have an important role in ensuring that the diet described on paper is adequately formulated and delivered to the cows. Routine scheduled activities, such as measuring the dry matter of forages, hand-mixing of total mixed ration (TMR) for one cow and comparing it with the machine-mixed TMR (termed the TMR test mix), and scoring the feed bunk to assess feed sorting and dry matter intake are important procedures that
help to ensure the successful delivery of a nutritional program. Assessing pasture conditions by periodic inspection of pasture is an important component of managing the nutritional program of herds that use management-intensive grazing. These quality control activities should be conducted routinely as part of the health and production management program.

There is probably no aspect of a dairy enterprise that has a wider impact than the feeding program, which has direct effects on production and growth. Many health problems on a dairy farm relate in some way to the feeding program, and a significant portion of the farm’s labor is spent planting, growing, harvesting, mixing, and feeding rations. Investment in equipment used in feeding programs is also an important capital cost. Small changes in feeding programs may bring about large changes in productivity, health, income, feed costs, labor allocation, cash flow, and debt. Thus the total savings from these small changes can be substantial, with one study showing that routine nutritional consultation by a veterinarian can save 14% of total feed costs even without accounting for improved production or health effects.

For these reasons, veterinarians who wish to serve their dairy clients on a whole-farm basis must become actively involved in the herd’s feeding program. Dairy herds are often fed unbalanced, expensive rations, but as a consultant independent from the feed company, a veterinarian can provide unbiased advice about the feed program. For example, a recumbent, hypocalcemic cow raises questions about dry-cow feeding, whereas an anestrous, thin cow with smooth ovaries raises questions about energy and dry matter intake (DMI) during early lactation. If the average mature equivalent milk production for the herd falls by 220 kg (500 lb), this generates the same sense of urgency as a cow with a prolapsed uterus. A dairy veterinarian cannot truly serve a client’s needs by practicing therapeutic medicine in isolation from the nutrition of the herd and thus must acquire skills to directly deal with nutrition problems.

As the average size of dairy herds increases, many dairy farmers now rely on a team of advisors rather than just one or two. Consequently, a nutritional consultant, local veterinarian, and remote specialist consultant may all be providing advice to a dairy farm, and thus awareness of and communication about the feeding program, and the indicators of performance of the farm, are critical. It imperative that, as part of the advisory team, the dairy veterinarian knows about dairy nutrition and is aware of, but preferably involved in, the ration formulation.

Levels of Nutritional Service

Having decided to be involved in a dairy’s feeding program, a first step is for the client and veterinarian to discuss and agree on the level of nutritional advice that is to be provided. This varies from herd to herd, depending on the veterinarian’s expertise, the client’s ability and interest, and the role of other consultants. There are essentially four levels of service that might be provided, as described next.

Level 1: Problem Identification and Analysis

At level 1, the veterinarian takes on the task of monitoring the dairy herd for indicators of nutrition-related problems. Many areas need to be monitored: production, milk composition, DMI, body scores, disease rates, heifer management and growth, and feed costs. Based on these measures, the veterinarian can identify problems as they arise, form and test hypotheses about likely causes, and interact with the client and other advisors as the problems are prioritized and addressed.

Level 2: Ration Analysis

Level 2 requires assessment of the adequacy of diets that are actually being fed to the cows. Problems of balance or economics are referred to the appropriate person, for example, if reformulation of a specific diet is needed. This involvement may be difficult to sustain if the person formulating the ration resents being “second-guessed,” but it can work well if a functional team approach is in place.

Level 3: Ration Formulation

If a dairy veterinarian takes responsibility for ration formulation, the veterinarian will need considerably enhanced skills in dairy nutrition, far beyond those traditionally taught at veterinary colleges. Typically, this involves using a computer program to formulate a balanced, least-cost ration for each class of animal. It requires expertise in the mechanics of how feeds are handled and fed to cows on a daily basis, and hence an intimate knowledge of the farm and its personnel and daily trends in the price and availability of feed components.

If not well managed, this level of service has several pitfalls because it lacks the on-farm follow-up, supervision of implementation, and monitoring of results that are included in level 4. There is a truism about feeding dairy cows that every cow has three rations: the one formulated, the one delivered, and the one actually eaten. The best feeding programs minimize the difference among these three rations. If the veterinary consultant’s role stops at formulation, then mistakes can occur in delivery and feed-bunk management that can doom the program to failure. However, if the program fails, it is the ration formulation that is most likely to be blamed.

Level 4: Total Program Consulting

Level 4 service includes the critical aspects missing from level 3 because the veterinarian plays an active role in implementing the feeding recommendations. Attention is paid to areas such as bunk management, cow comfort, feeding frequency and scheduling, quality control, and consistency of feeding management. Working closely with the producer, plans for future forage production can be generated, including attention to factors such as timing the harvest for maximum feed value. The monitoring described in level 1 is sustained, and timely adjustments and feedback are provided to ensure that the rations are accomplishing the desired ends. In the long term, this is the level of service that is most desirable for both the specialist dairy veterinarian and client. The producer benefits from the added supervision and support, and the veterinarian can assure the client that the program is implemented as it is intended. If it is not working, the total program can be modified, often with the veterinarian as part of a team that includes a nutritionist. When multiple consultants are used in larger herds, this team approach provides the owner with the best opportunity for expert advice, and the specialist dairy veterinarian is often best suited to be the “team leader.”

Nutritional Management of the Beef Breeding Herd

Good nutrition provides the essential basis for optimum productivity in cattle-breeding operations. Despite this, nutritional expertise has not been a traditional strength of many food-animal veterinarians.

Throughout the world, beef-breeding operations are generally range or pasture based. These operations are conducted in diverse environments, with great variation in nutritional management. In many countries, the area of pasture or rangeland required to maintain a cow–calf unit may vary from 0.5 to 1 ha (1 or 2 acres) in intensive high-rainfall regions to remote dryland areas. However, in general, the land area or amount of pasture necessary for production is related to local economic realities. This, in turn, is related to levels of managerial and resource inputs that differ markedly between regions, markets, and enterprises. Notwithstanding this variation, there are a number of principles of good nutritional management that can be universally applied to cattle-breeding operations. Regardless of region, an important consideration is that of maintaining or improving production (increasing income) while reducing costs per unit of production. In simple terms, financial return from a beef-breeding operation is a function of number of calves, their weaning weight, and price. On the cost side is the cost of maintaining the breeding females. This varies considerably between farms, both within and between regions. Although it can be influenced, the price received is generally not significantly controlled by the farm business. However, both
Nutritional Advice for Beef Feedlots

Beef feedlots frequently consult a qualified nutritionist to assist in the formulation of cost-effective rations. In this case the veterinarian should communicate regularly with the nutritionist to be aware of the composition of the diets and any changes that are planned. Because feed is the major portion of the cost per unit of body weight gain, it is imperative that the diet be the lowest-cost diet possible while providing nutrients that allow optimum growth and finishing. Most of the emphasis in feedlot nutrition has been on the development of cost-effective diets that support a maximum growth rate without any deleterious effects. Considerable information is available on the nutrient requirements for feedlot cattle and on the feeds and feeding systems used.

The precise specifications of the diets are the responsibility of the nutritionist, but the feedlot veterinarian is often able to evaluate the quality of the feed delivery system. This includes whether cattle are fed on time, whether the feed delivered to troughs is properly mixed, and whether feed intake is intermittent as a result of insufficient trough space, poor trough and pen design, inclement weather, and muddy or slippery ground. Any deviations should be discussed with feedlot managers and the consulting nutritionist, similar to the team approach suggested for large dairy herds.

Nutritional deficiency diseases are uncommon in feedlot cattle because cattle usually receive a diet that contains the nutrients required for maintenance and promotion of rapid growth. Diets prepared according to the Nutrient Requirements of Beef Cattle should meet all the requirements under most conditions.

Specific nutrient deficiencies are extremely rare because diets are prepared every few days or daily, and it would be highly unusual for a feedlot to use a feedstuff deficient in a specific nutrient for a prolonged period. However, such a situation may occur on a small farm or opportunistic feedlot that prepares its own diet with little thought to or no attention to the need to supplement homegrown feeds. Thus there are only a few nutrition-related diseases that may affect a well-managed feedlot, but these diseases may cause large economic losses when they occur.

They include the following:

- Carbohydrate engorgement (grain overload or lactic acidosis)
- Feedlot bloat or ruminal tympany
- Feeding errors, including accidental incorporation of an excessive amount of feed additives, such as monensin or urea; sudden unintended changes in the composition of the diet; and accidental feeding of the wrong dietary mix

Nutritional Advice for Swine-Herds

Veterinarians involved in health management of swine-herds must be well informed about the nutrient requirements of the different age groups of pigs. Feed constitutes 60% to 80% of the cost of producing a market pig, so every effort is needed to increase the efficiency of feed use. Surveys of well-managed pig farms in Alberta, Canada, found a 20% difference in feed costs, and it is estimated that in the industry the range in feed costs is likely to be near 50%. Reduction of the feed cost of the highest-costing farm to that of the lowest-costing farm would save that farm more than US$23,000 annually, a reduction in the cost of production of $6.80/pig. The trend is to use complete feeds formulated by feed company nutritionists familiar with the nutrient composition of local feedstuffs. With complete diets, specific nutrient deficiencies are uncommon.

The major problem is the efficiency of utilization of the different feeds throughout the life cycle of the pig. The nutrient requirements of the pig at various phases of growth, from birth to market weight and of breeding stock, are well established. The remaining questions relate to the amount of feed provided during the different growth phases of the pig to achieve optimum production and yield the best carcass. The following are some recommended practices for increasing efficiency of feed utilization:

- Provide well-balanced diets with adequate levels of amino acids, energy, vitamins, and minerals necessary to meet the particular demands of the pig at each stage of its life cycle. The diet depends on the demands, usually characterized as the growth rate or lean deposition, with feed intake being the supply function. Feed intake is limited by appetite, and thus other nutrients are matched to expected energy intake and subsequent growth.
- Use least-cost formulation to the extent that it is feasible. The least-cost energy source in most of the pig-rearing areas is corn, and the most common protein source is soybean meal.
- Restrict the level of a properly balanced diet for sows during gestation to avoid overfeeding. Sows that have lost excessive body weight in the previous lactation need supplemental feed during the dry period to avoid thin-sow syndrome.
- Ad-lib feeding for growing pigs is usually optimal unless the genotype deposits excess fat during the latter stages of growth.
- Market pigs as close to optimum slaughter weight as possible to maximize margin over feed costs.
- Avoid feed wastage by using well-designed feeding systems and proper adjustment of feeders.
- Use pelleting of diets to increase digestibility, especially of small grains, and to decrease feed wastage. However, pelleting does predispose pigs to gastroesophageal ulcers.

The feed efficiency of the pigs from weaning to market should be monitored regularly. It is often difficult to obtain accurate data for a specific group of pigs because a common feeding system for multiple groups is often used. However, the total amount of feed used and the total weight of pigs marketed will give an estimate of feed efficiency.

Although the nutrient requirements of pigs are well known, they do continue to change because of changes in growth and production characteristics. Pigs with high lean-growth rates require higher levels of amino acids to support their increased rate of body protein deposition. Similarly, high-milk-producing sows nursing large litters have increased amino acid requirements. The NRC in the United States provides an important service in establishing the nutrient requirements of swine and other species. The 10th edition of the Nutrient Requirements of Swine was published in 1998, and it includes areas such as modeling nutrient requirements and reducing nutrient excretion, particularly nitrogen and phosphorus, which can contribute to environmental pollution.

The approach used to produce estimates of nutrient requirements account for the
pig's body weight and the accretion of lean (protein) tissue, gender, health status, and various environmental factors. To accurately estimate nutrient needs of gestating and lactating sows, there is a need to account for body weight, weight gain during gestation, weight loss during lactation, number of pigs in the litter, weight gain of the litter (a reflection of milk yield), and certain environmental factors. A series of integrated equations is used to account for the many factors known to influence nutrient requirements. These provide the framework for modeling the biological basis of predicting requirements. The NRC models predict the levels of nutrients (outputs) needed to achieve a certain level of production under a given set of environmental conditions (inputs).

Five principles were used to develop the models: (1) ease of use by people with varying levels of nutritional expertise; (2) continued relevance; (3) structural simplicity; (4) transparency, so that all equations are available to the user; and (5) empirical data at the whole-animal level was used rather than data based on theoretical values. Three independent models were developed for growth, gestation, and lactation. The growth model estimates amino acid requirements of pigs from weaning to market weight, and the gestation and lactation models estimate energy and amino acid requirements of gestating and lactating sows.

Few revisions were needed from the previously published mineral requirements; higher dietary requirements for sodium and chloride in the young pig were established, and manganese requirements were increased from 10 to 20 ppm for gestating and lactating sows.

Feed composition tables are built from multiple databases on the nutrient composition of feeds, including the feed industry and datasets outside the United States and Canada.

The information on water was expanded, with more detailed information on the factors that influence water intake. Information on nonnutritive feed additives, such as antimicrobial agents, anthelmintics, microbial supplements, oligosaccharides, enzymes, acidifiers, flavors, odor-control agents, antioxidant pellet binders, flow agents, high-mineral supplements, and carcass modifiers, is also included.

Nutritional Advice for Sheep Flocks
The influence of nutrition on the reproductive performance of ewes has been a matter of concern for many years. Clearly, the relationship between the provision of nutrients and requirements for optimum reproductive performance is seldom ideal because of the wide range of environmental conditions and the seasonal breeding patterns of most sheep breeds. Prolonged periods of undernutrition often occur during midpregnancy, partly the result of the decline in feed availability and quality over that stage of the reproductive cycle and partly from the seasonal variability in pasture growth.

Prolonged moderate to severe undernutrition of ewes bearing twins in midpregnancy reduces placental development and can cause a significant reduction in lamb birth weight and increased lamb mortalities. Considerable progress has been made in understanding the principles of nutrition of sheep and in defining their nutrient requirements for maintenance, pregnancy, and lactation. It has been established that mortality rates are high in lambs with birth weights below the breed norm, and that after birth the absolute growth rates are lower in surviving light lambs than in heavier lambs of the same breed. The plane of nutrition and the size of the ewe have been recognized as major determinants of the fetal growth rate. Fetal growth retardation in undernourished ewes has a placentomal component, and thus factors that affect placental growth are highly relevant.

The 21-week gestation can be divided into a number of periods to consider the effects of nutrition on reproduction within each period. In the first 4 weeks of gestation, embryonic loss is the main sequelae of inadequate nutrition. During this period, it is generally recommended that the body condition score (BCS) of the ewe be maintained at an average of 3.0, on a scale of 1 (emaciated) to 5 (very fat), to minimize embryonic and early fetal loss. This is followed by a period of 2 months in which there is rapid growth of the placenta, but during which growth of the fetus in absolute terms is still small. Over this period, losses in body weight should not exceed 5%, and BCS should be maintained at 2.7 to 3.0. Finally, there is the phase from 90 days to parturition, in which gain in the mass of the fetus amounts to 85% of its birth weight, during which time nutrient intake must be increased if excessive weight loss in the ewe and light-birth-weight lambs are to be avoided.

Placental and Fetal Growth
Placental development in the pregnant ewe begins about 30 days after conception. The number of placentomes associated with each fetus is fixed at this time, but the total weight of the placentomes increases until about 90 days of gestation, after which there is little change. The factors that influence the ultimate size of the placenta and its weight include hormonal and nutritional factors, prolonged environmental heating of pregnant ewes, parity, and possibly genotype. However, by far the most important determinant is nutrition of the ewe. Moderately severe undernutrition during early and mid-pregnancy significantly reduces placental weight at term and causes chronic intrauterine growth retardation.

The size of the placenta is a major determinant of fetal growth. In well-fed ewes, the fetal growth rate until 120 days (17 weeks) of gestation is not positively correlated with placental weight, but fetal growth rate is limited by the size of the placenta during the last 3 to 4 weeks of pregnancy. However, when ewes are underfed, the influences of a lighter placenta on fetal growth rate are evident sooner, with placental weight and fetal growth positively correlated from as early as 90 days (13 weeks) of gestation. During the first 90 days of pregnancy, placental growth is reduced when ewes are moderately underfed. Light fetuses in ewes with placenta weights near the bottom of the normal range suffer chronic and progressive hypoxemia and hypoglycemia. This affects fetal metabolism, causing fetal death during late pregnancy, fetal hypoxemia during parturition, premature birth, and a high perinatal mortality rate from hypoglycemia and hypothermia, the latter being more severe in lighter lambs.

The extent to which ewes maintained on a fixed ration draw on their own body reserves in an attempt to meet the energy costs of pregnancy is determined by fetal weight. In well-fed ewes, fetal growth rate remains constant until at least 120 days of gestation and then decreases. However, the absolute growth rate increases markedly during the last 8 weeks of gestation, when fetal growth is most rapid, exceeding 100 g/day near birth. The growth rate among fetuses is highly variable, which accounts for birth weights ranging from 2 kg to over 7 kg. When ewes that have previously been well fed are severely underfed at any stage during the last 40 to 50 days of pregnancy, fetal growth rate decreases by 30% to 70% within 3 days. This demonstrates that mobilization of maternal reserves is substantially less than fetal requirements, emphasizing the importance of a continuous supply of good-quality feed during late pregnancy. The larger the fetal burden, the more susceptible an ewe is to hypoglycemia during underfeeding.

Refeeding after severe underfeeding can reverse the reduced growth rate of fetuses, but the response depends on the duration of the underfeeding. If the period of underfeeding is 16 days or less, the growth rate increases when ewes are refed, but there is no change when refedding occurs after 21 days of severe underfeeding. Moderate underfeeding of pregnant ewes for 85 days reduces the fetal growth rate irreversibly. Refeeding them in late pregnancy does not cause fetal growth rate to increase, but it does prevent further decreases after 120 days.

Lamb Losses
The major consequences of prenatal growth retardation are on lamb survival. Neonatal mortality increases markedly in many environments when the birth weight falls below 3 to 3.5 kg. Compared with normal lambs, low-birth-weight animals have reduced insulation because of the smaller number of wool
fibers, greater relative heat loss because of their larger surface area per unit of body weight, and a reduced capability to maintain heat production because of their lower fat and energy reserves. All of these factors increase their susceptibility to environmental stress and reduce their ability to compete with normal-sized siblings.

Underfeeding during pregnancy reduces available body lipids in lambs by about 47%, and it also decreases the lactose, lipid, and protein available in colostrum during the first 18 hours after birth by about 50%. Newborn lambs have to draw on body reserves of glycogen to maintain heat production during the first 18 hours after birth. Consequently, they depend heavily on colostrum and supplements, when these are provided, to avoid hypoglycemia and hypothermia.

The effects of maternal nutrition on udder development and on the production and yield of colostrum and milk in ewes have also been examined. In the 30 days before birth, there is a marked increase in the rate of mammary tissue growth in the ewe. In well-fed ewes with one or two lambs, large volumes of colostrum accumulate in the mammary glands during the last few days of pregnancy, and copious milk secretion begins soon after birth, with averages of 1800 to 2800 mL of colostrum and milk being produced during the first 18 hours. Udder growth rates show a similar pattern to fetal growth rates, such that the greatest increase in udder weight occurs in the last 30 days of gestation, and the weight of udder tissue is 30% to 40% of the total weight of the litter. Colostrum production is proportional to udder weight, but refeeding ewes a few days before lambing fills the udder tissue present rather than increasing udder tissue weight. In underfed ewes, accumulation of colostrum before birth is reduced markedly, lactogenesis is delayed, and the total production of colostrum and milk during the first 18 h averages only 1000 mL. Subsequently, for ewes on both planes of nutrition, milk production increases, reaching a peak about 1 to 2 weeks after birth. Underfeeding ewes from 105 days (15 weeks) of gestation can reduce the total yield of colostrum during the first 18 hours after birth by decreasing mammary tissue growth. Thus the preparation of colostrum and its subsequent rates of secretion are reduced. Improving the ewe’s nutrition from 1 hour after birth can increase the secretion rates of colostrum between 10 and 18 hours.

The growth rate of lambs during the first few weeks of life is positively correlated with birth weight. Low planes of maternal nutrition during late pregnancy and early lactation are generally associated with low birth weights, milk yields, and postnatal growth rates, and high planes of nutrition are associated with the opposite effects. A marked increase in the plane of maternal nutrition at birth can overcome the inhibitory effects on lactation and lamb growth rate of underfeeding in late pregnancy.

**Ewe Body-Condition Score**

Target condition scores for ewes at different stages of their reproductive cycle have been developed by research groups and departments of agriculture in many countries. These vary according to the predominant breeds and production systems in each country, and they can be quite different for a Merino, Dorset, or Friesian ewe used for wool, meat, or dairy production versus a dual-purpose enterprise producing both meat and wool. Consequently, readers should directly access information appropriate to the production systems of their clients. However, in general, the aim at breeding time is to have ewes with a BCS of 3.0 to 3.5, which ensures maximum ovulation rate. Ewes with a BCS of 3.5 at breeding can be allowed to lose no more than 5% of their body weight, steadily, during the second and third months of pregnancy, equivalent to approximately 0.5 to 1 BCS units. This mild degree of undernutrition enables good placental growth, establishing the basis for maximum fetal growth in the fourth and fifth months of pregnancy, during which the fetus achieves over 80% of its growth. During these final 2 months of pregnancy, there is a limit to the extent to which body-fat reserves can be used because excessive mobilization of fat deposits as a consequence of inadequate dietary energy supply leads to pregnancy toxemia. Ewes with a BCS below 3.0 should be managed to maintain that score.

In late gestation, the optimum BCS ranges from 2.75 to 3.0. In contrast, early lactation is a period in which body fat can be safely used to meet some of the high-energy demands of lactation. During this period, a loss of BCS of from 0.5 to 1.0 (equivalent to 5 kg of fat for a 70-kg ewe at mating) may occur. However, replacement of body fat, to increase the BCS to 3.0 to 3.5 before the next mating, is important to maximize ovulation rate and achieve optimum reproductive performance.

Winter shearing of pregnant ewes during the final 10 weeks of pregnancy can cause a significant increase in lamb birth weight by stimulating ewe appetite. However, this also increases the base energy requirements of the ewe at a feed-limiting time of the year in many production systems (e.g., winter for a spring-lambing flock). Thus it is not always an optimum or profitable system, but this will vary between production systems and different countries.

The nutrient requirements for maintenance, breeding, pregnancy, and lactation of ewes have been cataloged, and optimum feeding strategies for the breeding ewe can be formulated. The evaluation of the ewes’ ration during late gestation by monitoring plasma concentrations of the BHB has been described, and these evaluations have been used to provide nutritional advice in intensively managed flocks during late gestation. In more intensively managed flocks, achieving optimum reproductive performance requires adjusting feeding strategies and the nutrient value of the diet to meet the needs of each stage of the reproductive cycle. Requirement for metabolizable energy increases above maintenance levels from 8 to 12 weeks of pregnancy, increasing further in late pregnancy and lactation. During early lactation, when the energy requirements of prolific ewes exceed the voluntary intake from all but the highest-quality diets, body-fat reserves are used and then replenished toward the end of lactation, when milk yield declines, and in the period leading up to rebreeding.

The rapid growth of the fetus after 90 days of pregnancy and increased energy demand may require the feeding of cereal or legume concentrates, rather than hay, which has far lower metabolizable energy content. This is particularly true for ewes carrying twins or triplets.

In contrast to the ability of the ewe to use body reserves when the intake of energy fails to meet her needs, particularly in early lactation, there is little scope for sustaining production by drawing on body protein. For example, lactating ewes can lose up to 7 kg of body fat during a 4-week period in early lactation, when energy intake is below requirements. For ewes on a low-protein intake, the maximum daily loss of protein is around 26 g. Therefore it is important to meet the protein needs of the ewe during pregnancy, but especially during late pregnancy, to ensure adequate fetal growth, udder development, and colostrum production.

The estimates for the minimum protein requirements of the animal are based on distinguishing between the needs of the rumen microflora for rumen-degradable protein and of the host animal for additional undegraded dietary protein when rumen-degradable protein fails to meet those requirements. In practice, the dietary allowances for late pregnancy and early lactation are higher than the sum of the rumen-degradable protein and undegradable protein.

Deficiencies of Energy and Protein

DEFICIENCY OF ENERGY

ETIOLOGY

Insufficient quantity or quality of feed is a common nutritional deficiency and practical problem of feeding livestock. The term protein-energy malnutrition is used to describe a form of incomplete starvation in which a suboptimal amount of energy and protein is present in the diet. Such deficiencies typically occur when livestock are underfed, and often the two scenarios cannot be separated.

EPIDEMIOLOGY

A deficiency of energy is the most common production-limiting nutrient deficiency of farm animals. There may be inadequate amounts of feed available, or the feed may be of low quality (low digestibility). The availability of pasture may be inadequate because of overgrazing, drought, or snow covering. Alternatively, it may be too expensive to provide enough supplementary feed of the required quality, or the available feed may be of such low quality and poor digestibility that animals cannot consume enough to meet energy requirements. In some cases, forage may contain a high concentration of water, which limits total energy intake.

CLINICAL FINDINGS

The clinical findings of an energy deficiency depend on the age of the animal, whether or not it is pregnant or lactating, concurrent deficiencies of other nutrients, and environmental factors. In general, an insufficient supply of energy in young livestock causes decreased growth and delayed onset of puberty. In mature animals, there is reduced milk production and a shortened lactation. A prolonged energy deficiency in pregnant beef heifers will result in a failure to produce adequate quantities of colostrum at parturition. In mature animals, there is also a marked loss of body weight, especially when demand for energy increases in late pregnancy and early lactation. There are prolonged periods of anestrus, which reduces the reproductive performance of the herd. Primigravid females are particularly susceptible to protein-energy malnutrition because of their requirements for growth and maintenance. A deficiency of energy during late gestation can produce undersized, weak neonates with a high mortality rate, whereas abomasal impaction is associated with energy deficiency during prolonged cold weather, especially in pregnant beef cattle and ewes being wintered on poor-quality roughage. Heat loss from the animal to the environment increases considerably during cold weather, and when ambient temperatures are below the critical temperatures, the animal responds by increasing metabolic rate to maintain normal body core temperature. If sufficient feed is available when temperatures are below the lower critical temperature, ruminants will increase their voluntary feed intake to maintain body temperature. If sufficient feed is not available, the animal will mobilize energy stored as fat or muscle to maintain body temperature and thus lose body weight. In the case of ruminants and horses, if the feed is of poor quality, for example, poor-quality roughage, the increased feed intake may result in impaction of the abomasum and forestomachs in cattle and of the large intestine in the horse.

Cold, windy, and wet weather will increase the needs for energy, and the effects of a deficiency are exaggerated, often resulting in weakness, recumbency, and death. A sudden dietary deficiency of energy in fat, pregnant beef cattle and ewes can result in starvation ketosis and pregnancy toxemia. Hyperlipemia occurs in fat, pregnant or lactating ponies that are on a falling plane of nutrition.

Protein-energy malnutrition occurs in neonatal calves fed inferior-quality milk replacers that may contain insufficient energy or added nonmilk proteins, which may be indigestible by the newborn calf. A major portion of the body fat present at birth can be depleted in diarrheic calves deprived of milk and fed only fluids and electrolytes for 4 to 7 days. Feeding only fluids and electrolytes to normal, healthy newborn calves for 7 days can result in a significant loss of perirenal and bone-marrow fat and depletion of visible omental, mesenteric, and subcutaneous fat stores. The amount of body fat present in a calf at birth is an important determinant of the length of time an apparently healthy calf can survive in the face of malnutrition. Calves born from dams on an adequate diet usually have sufficient body fat to provide energy for at least 7 days of severe malnutrition. The absence of perirenal fat in a calf at 2 to 4 days of age suggests inadequate reserves of fat at birth and chronic fetal malnutrition.

DEFICIENCY OF PROTEIN

A deficiency of protein commonly accompanies a deficiency of energy. However, the effects of the protein deficiency, at least in the early stages, are usually not as severe as those of energy deficiency. Insufficient protein intake in young animals results in reduced appetite, lowered feed intake, inferior growth rate, lack of muscle development, and a prolonged time to reach maturity. In mature animals, there is loss of weight and decreased milk production. In both young and mature animals, there is a drop in hemoglobin concentration, packed cell volume, total serum protein, and serum albumin. In the late stages, there is edema associated with the hypoproteinemia. Ruminants do not normally need a dietary supply of essential amino acids, in contrast to pigs, which need a natural protein supplement in addition to the major portion of total protein supplied by the cereal grains. The amino acid composition of the dietary protein for ruminants is not critical because the ruminal flora synthesizes the necessary amino acids from lower-quality proteins and nonprotein sources of nitrogen.

CLINICAL FINDINGS

The clinical findings of a protein deficiency are similar to those of an energy deficiency, and the clinical findings of both resemble those of many other specific nutrient deficiencies and subclinical diseases. Protein-energy malnutrition in beef cattle occurs most commonly in late gestation and is characterized clinically by weakness, clinical recumbency, marked loss of body weight, a normal mental attitude, and a desire to eat. Cows with concurrent hypocalcemia will be anorexic. If the condition occurs at the time of parturition, there will be an obvious lack of colostrum. Calves of these cows may attempt to vigorously suck their dams, attempt to eat dry feed, drink surface water or urine, and bellow continuously. Affected cows and their calves may die within 7 to 10 days.

Protein-energy malnutrition is less common in dairy cattle because they are usually fed to meet the requirements of maintenance and milk production. Dairy calves fed inferior-quality milk replacers during periods of cold weather will lose weight, become inactive and lethargic, and may die within 2 to 4 weeks. Affected calves may maintain their appetites until just before death. Diarrhea may occur concurrently and be confused with acute undifferentiated diarrhea as a result of the enteropathogenic viruses or cryptosporidiosis. Affected calves recover quickly when fed cow’s whole milk.

Protein-energy malnutrition also occurs in sheep and, less commonly, in goats. Excessive dental attrition is a common cause in grazing sheep, which is exacerbated by the excessive ingestion of soil.
Differential Diagnosis

The diagnosis will depend on an estimation of the concentration of energy and protein in the feed, or a feed analysis, and comparing the results with the estimated nutrient requirements of the class of affected animals. In some cases, a sample of feed used several weeks earlier may no longer be available, or the daily feed intake may not be known. Marginal deficiencies of energy and protein may be detectable with the aid of a metabolic profile test. Specific treatment of livestock affected with protein-energy malnutrition is usually not undertaken because of the high cost and prolonged recovery period. Oral and parenteral fluid and electrolyte therapy can be given as indicated. The provision of high-quality feeds appropriate to the species is the most cost-effective strategy.

Prevention

The prevention of protein-energy malnutrition requires the provision of the nutrient requirements of the animals according to age, stage of pregnancy and production, the environmental temperature, and the cost of the feeds. Body-condition scoring of cattle and sheep can be used as a guide to monitor body condition and nutritional status. Regular analysis of feed supplies will assist in the overall nutritional management program. The published nutrient requirements of domestic animals are only guidelines to estimated requirements because they were determined in experimental animals selected for uniform size and other characteristics. Under practical conditions, all of the common factors that affect requirements must be considered.

Low-Milk-Fat Syndrome

In low-milk-fat syndrome, the concentration of fat in milk is reduced, often to less than 50% of normal, while milk volume is maintained. This syndrome is a significant cause of wastage in high-producing cows. Low concentration of fat in milk occurs with ruminal acidosis in cattle. The cause appears to be an increase in concentrations of conjugated linoleic acid in the diet, with subsequent reduction in lipogenesis in the udder. A supply of polyunsaturated fatty acids in the cows’ ration and alteration in fermentation in the rumen results in bihydrogenation of linoleic acid (abundant in oils and seeds) and formation of intermediate fatty acids in the rumen. These incompletely hydrogenated fatty acids are absorbed into the blood and have an inhibitory effect on lipogenesis. This syndrome occurs most commonly in cows on low-fiber diets, for example, lush, irrigated pasture or grain rations that are ground very finely or fed as pellets. Treatment is achieved by administration of sodium bicarbonate or magnesium oxide, which increase fiber digestibility and hence the propionate:acetate ratio. Magnesium oxide also increases the activity of lipo protein lipase in the mammary gland and increases uptake of triglycerides by the mammary gland from the plasma.

Diabetes Associated With Deficiencies of Mineral Nutrients

There is an enormous literature about mineral nutrient deficiencies in livestock, and thus it is not possible to comprehensively review it here, but some general comments are appropriate. In developed countries, severe deficiencies of single elements affecting very large numbers of animals now seldom occur. The diagnostic research work has been done, the guidelines for preventive programs have been outlined, and these have been applied in the field. Thus the major contributions to knowledge have already been made, and what remains is essentially applying and extending that knowledge. Some loose ends remain, including preventing the overzealous or unnecessary application of minerals, which can produce toxicoses or is simply not cost-effective; sorting out the relative importance of the constituent elements in combined deficiencies, characterized by incomplete response to single elements; and devising better ways of detecting marginal deficiencies.

At least 15 mineral elements are essential nutrients for ruminants. The macrominerals, required daily in gram amounts, are calcium, phosphorus, potassium, sodium, chloride, magnesium, and sulfur. The trace elements, or microminerals, are copper, selenium, zinc, cobalt, iron, iodine, manganese, and molybdenum. Improving trace-element nutrition of grazing livestock, in a way that is cost-effective and that meets consumer perceptions and preferences, is a continuing challenge.

Prevalence and Economic Importance

Despite experimental evidence that deficiencies or excesses of trace elements can influence growth, reproductive performance, or immunocompetence of livestock, there is often a lack of information on the prevalence and economic significance of such problems. Most published reports of trace-element-related diseases are case reports and thus provide insufficient information to assess prevalence and economic impact on a regional or national scale. Many reports are also compromised by commercial bias. Despite this, Food and Agriculture Organization/World Health Organization (FAO/WHO) Animal Health Yearbooks show that of the countries providing information on animal diseases, 80% report nutritional diseases of moderate or high incidence, and trace-element deficiencies or toxicities are involved in more than half of those whose causes were identified. As a specific example, in the United Kingdom it has been estimated that despite the activities of its nutritional and veterinary advisory services, and extensive supplementation, clinical signs of copper deficiency occur annually in approximately 1% of the cattle population. Copper deficiency can also predispose to increased mortality as a result of infectious diseases in lambs, and so it is likely that the economic losses from copper deficiency may be considerably underestimated even in developed agricultural economies.

Diagnostic Strategies

In developed countries with more advanced livestock industries, the emphasis is on disease prevention rather than therapy, and the cost-effective control of trace-element deficiencies is a matter of ongoing farmer education rather than research. Copper, cobalt, selenium, and iodine deficiencies can affect reproductive performance, appetite, early postnatal growth, and immunocompetence on a herd or flock basis, and thus emphasis is placed on identifying the risk of deficiency before clinical signs appear.

Monitoring the trace-element status of livestock is typically done by blood, saliva, or tissue analysis, or less commonly by measuring the concentration of the trace element in the diet. An alternative way of monitoring preclinical stages of a trace element deficiency is to identify and measure a biochemical indicator that reflects changes in the activity of an enzyme involved in a key metabolic pathway, such as vitamin B12 or glutathione peroxidase, which are indirect
measures of cobalt and selenium nutrition in sheep, respectively. To be useful, techniques should be able to predict the likely pathologic outcome of different suboptimal concentrations of a particular measure, and hence when it is clinically and economically justifiable to apply treatments or interventions. For example, a high proportion of grazing cattle become hypocupremic if maintained on pasture forage, but they don’t develop clinical signs of deficiency, and only a small percentage exhibit any physiologic response to the administration of copper. This illustrates the variation in the development of clinical signs of copper deficiency, which can be induced by a simple dietary deficiency or by interactions between copper and other elements in the diet, such as molybdenum, sulfur, and iron. There is also evidence that genetic variation influences the utilization of trace elements by livestock. For example, there are differences in dietary requirements for copper between some breeds of sheep. Sheep can also be selected for a high or low concentration of plasma copper, which can have profound physiologic consequences in the low-copper group.

Thus although it is known from soil maps and local knowledge where trace-element deficiencies occur, their prevalence and importance may be underestimated because subclinical deficiency may go unnoticed for prolonged periods.

DEFICIENCIES IN DEVELOPING COUNTRIES

In developing countries, deficiencies of trace elements are often hidden or confounded by gross nutritional deficiencies of energy, protein, phosphorus, and water, which affect postnatal growth and reproductive performance. Undernutrition is the most important limitation to herbivore livestock production in tropical countries, but mineral deficiencies or imbalances in soils and pasture forages, particularly of phosphorus, cobalt, or copper, are also responsible for poor reproductive performance and low growth rates.

PATHOPHYSIOLOGY OF TRACE-ELEMENT DEFICIENCY

The physiologic basis of trace-element deficiency is complex. Some trace elements are essential for the function of a single enzyme, whereas others are involved in multiple metabolic pathways. Consequently, a deficiency of a specific element may affect one or more metabolic processes and produce a variety of clinical signs in different classes of livestock. Furthermore, there is a wide variation in the clinical response to decreased blood or tissue concentrations of a trace element between individuals. For example, two animals in a herd or flock with the same concentration of copper in their blood may be in different body condition. Their susceptibility to clinical disease will also be influenced by their age, physiologic status (pregnant, lactating, or dry), genetic differences, and interactions with other trace elements. For example, there is good evidence that whereas dietary copper may be adequate for some breeds of sheep, such concentrations may be deficient, or even toxic, for others.

Dietary deficiency does not inevitably lead to clinical disease, but several factors interact and predispose the animal to clinical disease, including the following:

- Age—for example, late-term fetal lambs are highly susceptible to demyelination as a result of copper deficiency, which produces “swayback.”
- Genetic differences and individual variation in response to deficiency.
- Fluctuating demand for trace elements because of changes in growth, physiologic status (especially lactation), and diet.
- Substitution—the use of alternative metabolic pathways in response to a deficiency, such as selenium, which may incompletely protect sheep from white-muscle disease when the diet is deficient in vitamin E.
- Size of the functional reserves.

The soil and its parent materials are the primary sources of trace elements from which soil–plant–animal relationships are built. Soil maps created from geochemical surveys can help identify areas in which livestock are exposed to excessive ingestion or deficiencies of trace elements. Variations in the concentration of most trace elements in soils are quite wide, ranging from soils that are grossly deficient to those that are potentially toxic. The availability of trace elements to plants is controlled by their total concentration in the soil and their chemical form. Certain species of plants take up more trace elements than others, and the ingestion of soil can also have a profound effect on the nutrition and metabolism of some trace elements.

It is often difficult to determine the role of individual trace elements in deficiency states because many trace-element

</table>
deficiencies produce nonspecific and specific clinical signs, especially when complex interactions occur. Consequently, the dose–response trial still has a significant role to investigate complex or marginal deficiencies and whether a cost-effective response will occur on a particular farm. A properly conducted dose–response trial requires comparison of the response to treatment, typically a biochemical indicator and a measure of production, such as body weight, in a supplemented and control group. Ideally, animals should be randomly selected and allocated to groups, and the groups should be of sufficient size to reliably detect an economically significant difference (e.g., have a 95% chance of detecting a 1-kg difference in body weight). Where appropriate, the control (unsupplemented) group should be treated with the vehicle or inactive portion of the substance given to the supplemented group (a placebo). Additional requirements for a reliable dose–response trial include a careful appraisal of the reasons for conducting the trial, a suitable form of treatment, and a reliable biochemical method for monitoring the response to the trace element. Dose–response trials establish a link between a trace element and certain clinical signs. They can also identify factors that modify the response to a trace element and, importantly, provide some indication of the economic response to supplementation.

The ad hoc field observations made by veterinarians who make a diagnosis of a trace-element deficiency, followed by treatment or dietary changes, are subjective and usually lack controls. Nevertheless, they are useful in that they indicate the magnitude and variability of response that might be expected in future studies.

There are major challenges in predicting and diagnosing trace-element deficiencies in grazing livestock, including complex interactions between dietary constituents and the homeostatic mechanisms of the animal. Thus it is usually impossible to predict from the composition or analysis of the diet whether clinical signs of deficiency will occur. Consequently, assessment of the absorbable, rather than the total, concentration of elements in the diet is now considered to be more important in understanding the nutritional basis for the deficiencies, but tests of the livestock are a more definitive assessment of deficiency.

**LABORATORY DIAGNOSIS OF MINERAL DEFICIENCIES**

The diagnosis of mineral deficiencies, particularly trace-element deficiencies, relies heavily on the interpretation of the biochemical tests. This is because deficiencies of any one or more of several trace elements can result in nonspecific clinical abnormalities, such as loss of weight, growth retardation, anorexia, and inferior reproductive performance.

The interpretation of biochemical criteria of trace-element status is governed by three important principles: **relationship with intake, time, and function**. These are further explained as follows:

1. Relationship between the tissue concentrations of a direct marker and the dietary intake of the element will generally be sigmoid in shape (a dose–response curve). The important point on the curve is the intake at which the requirement of the animal is passed, which is the intake of the nutrient needed to maintain normal physiologic concentrations of the element and/or avoid impairment of essential functions. For several markers of trace-element status, the position on the $x$-axis at which the requirement is passed coincides with the end of the lower plateau of the response in marker concentration. Under these conditions, the marker is an excellent index of sufficiency and body reserves, but an insensitive index of deficiency. If requirement is passed at the beginning of the upper plateau, the marker is a poor index of sufficiency, but a good index of deficiency. This principle allows direct markers to be divided into storage and nonstorage types corresponding to the former and latter positions on the $x$-axis.

2. Nonstorage criteria can be divided into indicators of acute and chronic deficiency, and two types of relationships can be distinguished: a rapid, early decline in marker concentration followed by a plateau; and a slow, linear rate of decline. Markers with a slow, linear response will be good indices of a chronic deficiency, but unreliable indices of acute deficiency, because they cannot respond quickly enough. Conversely, the marker with a rapid, early decline will be a good index of acute deficiency, but an unreliable indicator for chronic deficiency if the low plateau is reached before functions are impaired. Those biochemical criteria that are based on metalloenzyme or metalloprotein concentrations in erythrocytes are of the slow type because the marker is incorporated into the erythrocyte before its release into the bloodstream, and thereafter its half-life is determined by that of the erythrocyte, which is 150 days or more. Metalloenzymes or metalloproteins in the plasma with short half-lives provide markers of the rapid type.

3. A deficiency can be divided into four phases: depletion, deficiency (marginal), dysfunction, and clinical disease. During these phases there are progressive changes in the body pools of mineral that serve as storage (e.g., liver for copper, bone for Ca and P), transport (e.g., plasma), and function (e.g., muscle enzymes) (Fig. 17-11). Depletion is a relative term describing the failure of the diet to maintain the trace-element status of the body, and it may continue for weeks or months without observable clinical effects when substantial body reserves exist. When the net requirement for an essential element exceeds the net flow of the absorbed element across the intestine, then depletion occurs. The body processes may respond by improving intestinal absorption or decreasing endogenous losses. During the depletion phase, there is a loss of trace element from any storage sites, such as the liver, during which time the plasma concentrations of the trace element may remain constant. The liver is a common store for copper, iron, and vitamins A and B₁₂.

![Fig. 17-11](image-url) The sequence of pathophysiological changes that can occur in mineral-deprived livestock, commencing with depletion and ending with clinical disease, and their relation to the body pools of that nutrient. (Reproduced with permission from Suttle NF. *Mineral Nutrition of Livestock*. 4th ed. Wallingford, Oxon, UK: CAB International; 2010 [Chapter 1].)
If the dietary deficiency persists, eventually there is a transition from a state of depletion to one of deficiency, which is marked by biochemical indications that the homeostatic mechanisms are no longer maintaining a constant level of trace elements necessary for normal physiologic function. After variable periods of time, the concentrations or activities of trace-element-containing enzymes will begin to decline, leading to the phase of dysfunction. There may be a further lag period, the subclinical phase, before the changes in cellular function are manifested as clinical disease. The biochemical criteria can be divided, according to the phase during which they change, into indicators of marginal deficiency and dysfunction. The rate of onset of clinical disease will depend on the intensity of the dietary deficiency, the duration of the deficit, and the size of the initial reserve. If reserves are nonexistent, as with zinc metabolism, the effects may be acute, and the separate phases become superimposed. The application of these principles to the interpretation of biochemical criteria of trace-element status is presented elsewhere where applicable, in the discussion of each mineral nutrient.

The definitive etiologic diagnosis of a trace-element deficiency will depend on the response in growth and health obtained following treatment or supplementation of the diet. The concurrent measurement of biochemical markers will aid in the interpretation and validation of those markers for future diagnosis. The strategies for anticipating and preventing trace-element deficiencies include regular analysis of the feed and soil, which is not highly reliable, and monitoring samples from herds and flocks to prevent animals from entering the zone of marginal trace-element deficiencies that precedes the onset of functional deficiency. The decision to intervene can be safely based on the conventional criteria of marginal trace-element status.

**Infectious Diseases Primarily Affecting the Reproductive System**

This chapter presents information related to important and selected livestock pathogens that affect not only the fertility but also the health of animals, and in some cases, such as bovine brucellosis, the health of humans. It is worth noting that national control and eradication campaigns against *Brucella abortus* infection in cattle played, and continue to play, an important global role in expanding the veterinary profession. More recently, the worldwide spread of porcine reproductive and respiratory syndrome (PRRS) virus during the last 20 years has had a marked economic impact on the swine industry. As a consequence, PRRS is currently one of the most intensively researched diseases of livestock.

Readers seeking detailed information related to reproductive performance, the estrous cycle, conception, pregnancy, and parturition are directed to the many excellent textbooks that address these subjects.

**INDUCTION OF PARTURITION CALVES**

The induction of parturition in pregnant cows during the last 6 weeks of gestation by the parenteral injection of corticosteroid with or without prostaglandin F2α (PGF2α) has raised the question of animal welfare and of the possible effects of prematurity on the disease resistance of the newborn calf. The induction of premature parturition in cattle has found application in the following areas:

- With pastoral-based dairy production, synchronization of the calving period has allowed maximal utilization of seasonally available pastures by the synchronization of peak demand for dry matter intake with spring flush in pasture growth. In pastoral-based herds with breeding for seasonal calving, late-calving cows will be induced and these average approximately 8% of the herd.
- Ensuring that calving coincides with the availability of labor to facilitate observations and management of calving and to overcome the inconvenience caused by late-calving cows.
- Minimizing dystocia in small heifers and animals with exceedingly long gestation periods (past due).
- The therapeutic termination of pregnancy for various clinical reasons.
- As an aid in the control of milk fever in combination with parental administration of vitamin D analogs. A variety of short-acting and long-acting corticosteroids have been used. A single injection of a short-acting formulation is used when it is desirable to induce calving within the last 2 weeks of gestation. Earlier in pregnancy short-acting corticosteroids were found to be insufficiently reliable to induce parturition, which has led to the common use of long-acting corticosteroid formulations. A variety of protocols to induce premature parturition (3–6 weeks before due date) are used in practice; the main issue is the poor predictability of the time of calving relative to treatment when using long-acting corticosteroids. Common protocols use a second treatment with short-acting corticosteroids or the administration of PGF2α 50 to 10 days after the initial treatment. The use of PGF2α at least 9 days after treatment with long-acting corticosteroids was found to reliably narrow down the calving time, with the great majority of all cows calving within 72 hours of PGF2α treatment. The use of PGF2α did not improve the viability of the premature neonates or their survival rate.

For cattle near term (within 2 weeks of due date) the use of short-acting corticosteroid formulation is more appropriate with parturition generally occurring within 2 to 4 days posttreatment.

The **mortality rate** of induced calves is considerable and can exceed 30%, particularly when dams are induced at or before the eighth month of gestation. Mortality in calves born as a result of induced parturition is primarily a result of prematurity, and...
Calf mortality is generally low when calving is induced within 12 days of parturition, although there are welfare concerns. The calves born earlier in pregnancy after using long-acting corticosteroids are usually lighter in weight, lethargic, and slow to stand and to suck properly. The serum immunoglobulin concentration was found to be lower in calves born from dams induced with long-acting corticosteroids because of interference with intestinal absorption by the corticosteroid. Up to 60% of calves born following induction with long-acting corticosteroids are at risk for failure of transfer of passive immunity. The colostrum available to such calves also has a reduced immunoglobulin content, and there may also be a reduction in the total volume of colostrum available from the induced-calving cows. Immunoglobulin absorption rates were not impaired when short-acting corticosteroids are used to induce calving close to term.

Artificial induction of parturition is an important risk factor for retention of the placenta, and the incidence is reported to vary from 20% to 100%. Subsequent reproductive performance of induced cows can be impaired. A risk for acute gram-negative bacterial infections is reported in a low (0.3%) proportion of cows following induction with dexamethasone. The use of long-acting corticosteroids was also associated with a higher incidence of photosensitization in treated heifers. In a study where partus induction was systematically used in cows that exceeded a gestation length of 282 days, no detrimental effects on calf viability, cow health, and productive and reproductive performance during lactation were found compared with untreated control animals. The incidence of retained fetal membranes in untreated animals was not recorded in this study and could thus not be compared with treated animals.

When parturition is induced in large herds of beef cattle, particularly with a high percentage of heifers, increased surveillance will be necessary after the calves are born to avoid mismothering. Every attempt must be made to establish the cow–calf pair (neonatal bond) and move them out of the main calving area. Heifers that disown their calves must be made to establish the cow–calf pair (neonatal bonding) and the three essential criteria are

- A gestational length of more than 330 days.
- Substantial mammary development and the presence of colostrum in the mammary gland with a calcium concentration greater than 10 mmol/L.
- Softening of the cervix.

The rise in calcium concentration is the most reliable predictor of fetal maturity and milk calcium concentrations above 10 mmol/L, in combination with a concentration of potassium that is greater than sodium, are indicative of fetal maturity. Commercial milk test strips are available for estimating mammary secretion electrolyte concentrations; however, it is recommended that testing be done in an accredited laboratory.

In mature foals, head lifting, sternal recumbency, and evidence of suck reflex occurs within 5 minutes of spontaneous full-term deliveries. The foal can stand within 1 hour and suck the mare within 2 hours. The behavior and viability of the premature foal after induced parturition have been described. The overall survival rate of foals delivered from induced parturition before 320 days' gestation was 5%. Four patterns of neonatal adaptation were observed on the basis of righting, sucking, and standing ability. If the suck reflex was weak or absent and the foals were unable to establish righting reflexes, the prognosis of survival was poor. Foals born before 300 days' gestation did not survive for more than 90 minutes; foals born closer to 320 days' gestation had a better chance of survival and exhibited behavioral patterns of adaptation.

In addition to the potential delivery of a premature or weak foal, other adverse effects of induction can be dystocia, premature placental separation, and retained placenta.

**FOALS**

The induction of parturition in mares for reasons of economy, management convenience, concern for prolonged gestation, or clinical conditions such as prepubic tendinosis, rupture or research and teaching is now being practiced.

Foaling can be induced with oxytocin, ideally administered as an intravenous (IV) drip over 15 to 30 minutes, and occurs within 15 to 90 minutes of its administration. High doses of oxytocin are potentially dangerous to the foal and low doses (10–20 IU) are preferred. Glucocorticoids, and antiprogestagens that are effective in inducing pregnancy in other species, are either ineffective in the mare or capricious in their efficacy and can also be associated with adverse effects on the foal.

Prostaglandin F2α and its analogs have been used for partus induction in the mare and low doses (5–12 mg intramuscularly [IM]) may be effective at term, but repeated treatments may be required. The time interval between treatment and delivery is difficult to predict and can range from 1 to 48 hours. The use of PGF2α for partus induction in mares has been discouraged because considerable risks such as premature placental separation and foal death that have been associated with this treatment. Induction of parturition in the mare is not without risk and has been associated with the birth of foals that are weak, injured, or susceptible to perinatal infections. The period of fetal maturation is relatively short in the horse and is considered to be the last 2 to 3 days' gestation. Because spontaneous parturition in healthy mares can occur between 320 and 360 days, there is the risk of delivering a foal that is premature and nonviable. Fetal maturity is the major prerequisite for successful induced parturition, and the three essential criteria are

- A gestational length of more than 330 days.
- Substantial mammary development and the presence of colostrum in the mammary gland with a calcium concentration greater than 10 mmol/L.
- Softening of the cervix.

The rise in calcium concentration is the most reliable predictor of fetal maturity and milk calcium concentrations above 10 mmol/L, in combination with a concentration of potassium that is greater than sodium, are indicative of fetal maturity. Commercial milk test strips are available for estimating mammary secretion electrolyte concentrations; however, it is recommended that testing be done in an accredited laboratory.

In mature foals, head lifting, sternal recumbency, and evidence of suck reflex occurs within 5 minutes of spontaneous full-term deliveries. The foal can stand within 1 hour and suck the mare within 2 hours. The behavior and viability of the premature foal after induced parturition have been described. The overall survival rate of foals delivered from induced parturition before 320 days' gestation was 5%. Four patterns of neonatal adaptation were observed on the basis of righting, sucking, and standing ability. If the suck reflex was weak or absent and the foals were unable to establish righting reflexes, the prognosis of survival was poor. Foals born before 300 days' gestation did not survive for more than 90 minutes; foals born closer to 320 days' gestation had a better chance of survival and exhibited behavioral patterns of adaptation.

In addition to the potential delivery of a premature or weak foal, other adverse effects of induction can be dystocia, premature placental separation, and retained placenta.

**PIGLETs**

The induction of parturition of gilts and sows on days 112, 113, or 114 of gestation is highly reliable and can be achieved by a single IM injection of 175 μg of cloprostenol or 5 to 10 mg of PGF2α. The sows farrow approximately 20 to 36 hours later. Synchronization of farrowing can be improved by administration of oxytocin (5–30 IU) 20 to 24 hours after injection of PGF2. Induction of parturition has been used on large-scale farms to allow a concentration of labor, to improve supervision and care at the time of farrowing, to reduce the incidence of the mastitis/metritis/agalactia syndrome, and to reduce the percentage of stillborn piglets. The end day of a batch farrowing system can be fixed and weekend farrowing avoided. The subsequent fertility of the sows is not impaired. Induction on day 110 may be associated with a slight increase in perinatal mortality.
although the male partners of female twins reported in goats, sheep, and pigs, and, utero. Sex chromosome chimerism is also types that originated in separate individuals. individuals that contain two or more cell chromosome (R-2).

FREEMARTINISM IN CALVES
A freemartin is defined as a sterile female partner of a pair of heterosexual twins. In cattle, 92% of females born cotwins to males are freemartins.

In normal calves, the chromosomal identification of females is 60,XX (60 chromosomes, both X chromosomes) and of males is 60,XY (the Y being smaller and not readily paired with its opposite X chromosome).

The freemartin is the classical example of the chimera in cytotogenetics. They are the individuals that contain two or more cell types that originated in separate individuals. The only way in which a chimera can develop is via the fusion of circulations or zygotes in utero. Sex chromosome chimism is also reported in goats, sheep, and pigs, and, although the male partners of female twins are usually anatomically normal, they often have reduced fertility. Bulls born cotwin with freemartin females may also be chimeric and have low reproductive efficiency.

The diagnosis of freemartinism has been based on physical examination, karyotyping, or blood typing, and each has its limitations. There is variation in the degree of reproductive tract abnormalities in freemartins. The external genitalia may appear normal, the vulval hair may be coarser than usual, or the clitoris may be enlarged. The vagina is generally expected to be shorter than normal. The cervix, uterus, uterine tubes, and ovaries may be absent, present in underdeveloped form, or may appear normal on rectal palpation.

Special cytogenetic techniques are also available that facilitate the diagnosis of freemartinism in a female calf of a male–female twinning. In freemartins (phenotypically female, but also carrying male cells) there is a mixture of mostly 60,XX chromosomes to a cell and a small proportion of 60,XY cells. A large number of cells need to be analyzed if only the freemartin calf is available, because the proportion of abnormal cells present may be as low as 2%. It is, however, possible to make a diagnosis on the examination of 10 to 20 cells, provided the male twin is also analyzed; the female may have very few XY chromosomes, but the male will have a very high proportion of XX chromosomes. This technique is much more accurate than blood group analysis or clinical observations of a short vagina, enlarged clitoris, and the presence of a vulval tuft of hair. Karyotyping is a definitive method of freemartin diagnosis, but it is tedious, time-consuming, and expensive. Blood typing analysis may be performed on both the male and female cotwins to demonstrate two blood group populations, but it is expensive and requires blood samples from both cotwins.

The polymerase chain reaction (PCR) method of freemartin diagnosis using sex-specific DNA sequences is rapid, accurate, relatively simple, and inexpensive to perform, and a blood sample is required only from the female cotwins. It allows for the accurate decision of freemartinism down to a level of 0.05% of male chimeric cells present.

ETIOLOGY
The buller steer syndrome is a behavioral problem in cattle confined in feedlots of unknown etiology. Within a pen of cattle, one or more cattle persistently ride a particular individual or individuals of the group. The ridden animals are referred to as bullers. There have been several suspect etiologies. Improper placement of hormonal growth implants has been suspected as being associated with this behavioral problem.

EPIDEMIOLOGY
Occurrence
The syndrome occurs only in cattle in feedlots. A recent survey conducted among U.S. feedlots revealed a feedlot prevalence of 68.8% of all surveyed feedlots and an animal level prevalence of 2.8%. The prevalence increases with increasing weight and age. The case fatality has been estimated at 1%. The incidence of occurrence is higher in the summer and the fall and during the first 30 days of the feeding period.

Epidemiologic studies indicate that bullers occur as a point source epidemic with the cause occurring soon after cattle arrive in the feedlot and mingle into pen groups. The peak incidence of bullers occurs much sooner after arrival and declines much quicker in older cattle. Bullers occur significantly sooner after mixing in older cattle than in younger cattle. The pen prevalence also increases as cattle become older on arrival at the feedlot and are more aggressive. As the prevalence of intact bulls increases in pens of cattle, so does the prevalence of bullers, presumably caused by more aggressiveness in the bulls.

Risk Factors
Postulated causative and risk factors include the incorrect timing and administration of hormonal growth implants, reimplantation and double dosing, estrogenic substances in feeds, pheromones in the urine of certain cattle, improper or late castration of young cattle, daily feedlot management, weather and seasonal factors, disease, group size, and dominance behavior. However, these factors have not been well substantiated, and controlled studies have found little influence of implant type and implant timing on buller incidence.

The mixing and confinement of unfamiliar cattle into pen groups, with subsequent agonistic interactions because these cattle established a social hierarchy, are considered as important risk factors. Both riding behavior and antagonistic behavior cease once cattle establish a stable social hierarchy. This suggests that riding behavior and subsequent identification of bullers is associated with this dominance behavior. It is possible that when a dominant animal becomes ill in a pen, other more subordinate animals in the pen that were previously subdued in
Blackshaw JK, Blackshaw AW, McGlone JJ. Buller steer hierarchy. into their designated pen by allowing them improve the chance of settling them back to their designated pen to prevent severe riding-related injuries. The high rate of risk pen to prevent injury and even death from hair and have extensive subcutaneous being ridden. Type 2 bullers are animals that appear low in pen and type 1 bullers are rapidly damaged. cattle. There can be several rider cattle in a estrus and do not move away or show ago stand as if they were a heifer in among individuals was greatest among the tion between illness, mortality, and bullers of illness and mortality (from bacterial pneumonitis) than other steers. The association between illness, mortality, and bullers among individuals was greatest among the oldest yearling steers.

CLINICAL FINDINGS
Two types of bullers are identified. Type 1 or true bullers stand as if they were a heifer in estrus and do not move away or show agnostic behavior when being mounted by rider cattle. There can be several rider cattle in a pen and type 1 bullers are rapidly damaged. Type 2 bullers are animals that appear low in social dominance. They use aggression to discourage riders and will lie down to avoid being ridden.

Affected animals show areas of denuded hair and have extensive subcutaneous hemorrhage. The hematomas may become infected and develop to subcutaneous pockets of pus and gas. Other traumatic injuries, such as limb fractures, also occur.

CONTROL
Management of the syndrome has usually involved identification and removal from the pen to prevent injury and even death from riding-related injuries. The high rate of risk of illness and mortality in bullers relative to other feedlot steers suggests that bullers should always be checked for evidence of illness in addition to their removal from their designated pen to prevent severe riding-related injuries. Treating sick bullers may improve the chance of settling them back into their designated pen by allowing them to resume their original position in the social hierarchy.

APPLICATION
Etiology Brucella abortus
Epidemiology Major cause of abortion in cattle in countries without a national control program. Undulant fever in humans; is an important zoonosis. Sexually mature animals susceptible; outbreaks occur in first-calf heifers, older cows are infected but do not abort. Transmitted directly from the infected animal to the susceptible animal by uterine discharges. Congenital infection occurs. Infection in wildlife species but significance to domestic animals unknown. Infection introduced into herd by unknown infected carrier animal. Natural infection and vaccination result in immunity to abortion but not infection, and infected animals remain serologically positive for a long time.

Clinical pathology Serology. Serum agglutination test is standard test. Rose Bengal test (rapid screening test). Complement fixation test. ELISA test. Milk ring test. False-positive reactors are a major problem.

Lesions Necrotizing placentitis, inflammatory changes in fetus.

Diagnostic confirmation Culture organism from fetus. Positive serologic test in unvaccinated animal.

Treatment No treatment.

Control Test and reduce reservoir of infection. Quarantine. Depopulation. Vaccination to reduce incidence of abortion and percentage of infected animals. Eradication on herd and area basis by test and cull.

ELISA, enzyme-linked immunosorbent assay.

ETIOLOGY
Brucella abortus, a gram-negative, facultative intracellular coccobacillus of the family Brucellaceae, is the organism responsible for bovine brucellosis. B. abortus is one of 10 species with validly published names, including B. melitensis, B. abortus, B. suis, B. ovis, B. neotomae, B. canis, B. ceti, B. pinnipedialis, B. microti, and B. inopinata, each of which has specific host preferences.1 B. abortus is responsible for bovine brucellosis, B. melitensis is the main causative agent of brucellosis in small ruminants and men, B. suis for brucellosis in swine, and B. ovis in sheep. B. abortus has eight recognized biotypes (1–7, 9) of which the most prevalent are 1–4, and 9.2 Approximately 5% of infections are from biotype 1. Biotype 2 was isolated in an outbreak of brucellosis in cattle in Canada in 1986. In the United States, biotypes 1 to 4 are found.

EPIDEMIOLOGY
Occurrence and Prevalence of Infection
Bovine brucellosis has a worldwide occurrence and, according to the Food and Agriculture Organization (FAO), the World Health Organization (WHO), and the World Organization for Animal Health (OIE), is still one of the most important and widespread bacterial zoonoses in the world. The prevalence of infection varies considerably among herds, areas, and countries. Many countries have made considerable progress with their eradication programs, and some have eradicated the disease. However, in other countries brucellosis is still a serious disease facing the veterinary and medical professions. Currently, Australia, New Zealand, Canada, Japan, and 16 member states of the European Union (EU) have a status as officially brucellosis free.3–5 Bovine brucellosis remains prevalent in several southern European countries and the Mediterranean basin. The seroprevalence of bovine brucellosis in the Kars district of Turkey between 2004 and 2006 was determined to be around 34%.4 In Greece 0.97%, in Italy 0.51%, in Portugal 0.19%, in Spain 0.07%, and in the UK 0.09% of all cattle herds were positive for brucellosis in 2012.6 Although bovine brucellosis has been reported from Egypt (biotype 1), Iran (biotype 2), and Sudan (biotype 6), little is known about the infection prevalence in the region.7

In the United States, the entire country is classified as class free for bovine brucellosis. Nevertheless, infection remains highly prevalent in the wildlife population in the Greater Yellowstone area, with occasional spread to cattle. Repeated incidents of brucellosis-infected cattle in Montana, Idaho, and Wyoming have been reported in recent years.8 Bovine brucellosis remains an important bacterial disease in Mexico, with biotypes 1–6 the most prevalent. Although limited epidemiologic data are available for Central America, the disease seems to prevail widely, with an estimated animal prevalence of between 4% and 8% and a (dairy) herd prevalence between 10% and 25%.5 In South America Chile made great progress toward eradicating the disease, but it remains prevalent in Venezuela (animal seroprevalence 3%–4%), Argentina (animal seroprevalence 2%–3%), and Brazil.9

The livestock prevalence was estimated at 8.2% in East Africa, 15.5% in West Africa,
14.2% in South Africa, and 13.8% in North Africa.

Cattle
Infection occurs in cattle of all ages but is most common in sexually mature animals, particularly dairy cattle. Abortions are most common during outbreaks and primarily occur in unvaccinated heifers over 5 months pregnant. Bulls are affected with orchitis, epididymitis, and seminal vesiculitis.

Camelids
Brucellosis has been reported in the one-humped (Camelus dromedaries) and two-humped camel (C. bactrianus) and New World camelids such as llama (Lama glama), alpaca (Lama pacos), guanaco (Lama guanicoe), and vicuna (Vicugna vicugna) and was related to contact with small and large ruminants infected with either B. abortus or B. melitensis.

Wildlife Species
The infection has been observed in American and European bison (Bison bison, B. bisonas); domestic buffalo (Bubalus bubalis); elk (Cervus elaphus canadensis); deer; coyotes; wild opossums; and raccoons, moose, and other wild and domesticated ruminants. Infection of moose with B. abortus biovar 1 is highly fatal, and it is likely that the moose is a dead-end host for brucellosis. Experimental inoculation of the organism into badgers results in the development of antibodies and elimination of the organism, which indicates that the badger is relatively resistant to infection and unlikely to be a reservoir of the organism.

Bison and elk are potential reservoirs of bovine brucellosis and have been associated with recurrence of bovine brucellosis in the Greater Yellowstone area in the United States. Brucellosis associated with B. abortus was first detected in bison (B. bison) in Yellowstone National Park in 1917 and has been present ever since. Bison can remain latently infected with virulent B. abortus until attainment of reproductive age despite extensive use of vaccination and serologic testing.

Cattle and bison appear to maintain B. abortus at higher seroprevalence than other ungulate species. The seroprevalence in the Yellowstone bison and elk population is estimated with 40% to 60% and 22%, respectively. This has been associated with physiologic and immunologic characteristics common to bovine species but is probably also caused by typical behavioral patterns of large social groups and the parturient behavior of bison dams that tend to calve within groups that facilitate disease transmission through direct contact around parturition. In contrast elk dams segregate themselves during the parturient period and meticulously clean the birthing site, considerably reducing the risk of disease transmission through direct contact.

Disease transmission may, however, be common during the abortion period in the last trimester of pregnancy from February to April, when many elk congregate in large groups on lower elevation winter habitat that overlaps with cattle-grazing areas. From 2009 to 2011 eight infected cattle or captive bison herds were detected in Wyoming and Montana and all episodes were genetically or epidemiologically linked to elk, suggesting that spillover transmission from elk to cattle is epidemiologically more important than transmission from bison to cattle. This has been explained with the continuously increasing elk population, which is currently above management target values in many areas of the Greater Yellowstone area and the greater mobility of free-ranging elk.

Horses
In horses the organism is often found in chronic bursal enlargements as a secondary invader rather than a primary pathogen. It is commonly present with Actinomyces bovis in fistulous w ithers and poll evil. It has also been identified as a cause of abortion in mares. A serologic survey of horses over a period of 8 years revealed that 8% to 16% of serum samples were positive. However, experimentally infected horses do not excrete the organism in sufficient numbers to infect susceptible in-contact cattle.

Pigs and Sheep
The organism can be recovered from naturally infected pigs and, although not normally pathogenic in this species, may occasionally cause abortion. The disease occurs naturally in sheep exposed to infected cattle, which has significant implications for brucellosis eradication.

Dogs
Naturally acquired B. abortus infection can occur in dogs associated with infected cattle. Although farm dogs are not generally considered to be a major reservoir of B. abortus, the organism has been isolated from dogs on a farm in which several cattle were serologically positive for brucellosis, and dogs should be included in any investigation and eradication of the disease.

Methods of Transmission
Parturition/Abortion

The risk posed to susceptible animals following parturition or abortion of infected cattle depends on three factors:

- Number of organisms excreted
- Survival of these organisms under the existing environmental conditions
- Probability of susceptible animals being exposed to enough organisms to establish infection

The organism achieves its greatest numbers in the contents of the pregnant uterus, the fetus, and the fetal membranes, all of which must be considered as major sources of infection. The numbers of organisms in the tissues of two naturally infected cows and their fetuses were as follows: umbilicus $2.4 \times 10^8 - 4.3 \times 10^7/g \ - 1.4 \times 10^7/g$. This illustrates the potentially large numbers of organisms that can be shed and to which other animals and humans are potentially exposed. However, the numbers of organisms decrease when uterine discharges are cultured at sequential parturitions, and a substantial number of uterine samples from infected cows are culture negative at the second and third parturition following challenge.

Transmission
The disease is transmitted by ingestion, penetration of the intact skin and conjunctiva, and contamination of the udder during milking. The organism does not multiply in the environment but merely persists, and the viability of the organism outside the host is influenced by the existing environmental conditions. Grazing on infected pasture, or consuming feedstuffs or water supplies contaminated by discharges and fetal membranes from infected cows, and contact with aborted fetuses as well as infected newborn calves are the most common methods of spreading the disease.

Intraherd spread occurs by both vertical and horizontal transmission. Horizontal transmission is usually by direct contamination and, although the possibility of introduction of infection by flies, dogs, rats, ticks, infected boots, fodder, and other inanimate objects exists, it is not significant relative to control measures. The organism is ingested by the face fly but is rapidly eliminated, and there is no evidence for a role in natural transmission. Evidence exists for horizontal, dog-to-dog, cattle-to-dog, dog-to-cattle, and dog-to-human transfer of infection. The most likely and effective means of cattle-to-dog transfer is exposure to aborted fetuses or infected placental membranes, because dogs commonly ingest the products of parturition.

Spread Between Herds
Movement of an infected animal from an infected herd to a susceptible noninfected herd is a common method of transmission. The rate of spread will depend on the level of surveillance testing. In Great Britain, which is officially brucellosis free, 20% or more of both beef and dairy cattle more than 24 months old are tested routinely. A simulation model indicates that reducing the level of testing would have a major effect on the rate of spread of infection, should it be imported.

Spread Between Countries
(Breach of Biosecurity)
A quantitative risk assessment model to determine the annual risk of importing brucellosis-infected breeding cattle into Great
Natural exposure to field strains occurs.

The herd characteristics and the results of the first herd test may be used as predictors of the potential presence or absence of *B. abortus* in herds with reactors to the tuberculin test. The presence of only single suspicious reactors on the first test is a reliable predictor of lack of infection. The presence of one or more positive reactors on the first herd test is a reliable predictor of the presence of infection.

**Risk Factors**
The risk factors that influence the initiation, spread, maintenance, and/or control of bovine brucellosis are related to the animal population, management, and the biology of disease. The variables that contribute significantly to seropositive animals are
- Size of farm premises
- Percentage of animals on a premises that are inseminated artificially
- Size of investment in livestock
- Number of cows that aborted in the previous year, whether or not dairying is the major agricultural activity of the premises
- Policy of the owner regarding disposal of reactor animals

The longer infected animals are in contact with the remainder of the herd, the greater will be the ultimate number of seropositive animals. In a defined geographic area in northern Mexico where a brucellosis control program did not exist, the greatest percentage of seropositive animals was related to larger farms, poor artificial insemination technique, and small financial investment in the farm.

**Animal Risk Factors**
Susceptibility of cattle to *B. abortus* infection is influenced by the age, sex, and reproductive status of the individual animal. Sexually mature, pregnant cattle are more susceptible to infection with the organism than sexually immature cattle of either sex. Natural exposure to field strains occurs
primarily at the time of parturition of infected cows. The greater the number of infected cows that abort or calve, the greater the exposure risk to the other cattle in the herd. An important application of this observation is that infected cows need to be removed from the herd before parturition. Young cattle are less susceptible to \( B. \) abortus than older, sexually mature cattle. Susceptibility appears to be more commonly associated with sexual maturity than age. Young, sexually immature cattle generally do not become infected following exposure, or recover quickly. Susceptibility increases with pregnancy and as the stage of gestation increases. The probability of isolation of the organism at parturition increased from 0.22 to 0.90 as fetal age at exposure of nonvaccinated heifers increased from 60 to 150 gestation days.

Management Risk Factors

The spread of the disease from one herd to another and from one area to another is almost always caused by the movement of an infected animal from an infected herd into a noninfected susceptible herd. The unregulated movement of cattle from infected herds or areas to brucellosis-free herds or areas is the major cause of breakdowns in brucellosis eradication programs. A case-control study of brucellosis in Canada indicated that herds located close to other infected herds and those herds whose owners made frequent purchases of cattle had an increased risk of acquiring brucellosis. Once infected, the time required to become free of brucellosis was increased by large herd size, by active abortion, and by loose housing.

Pathogen Risk Factors

\( Brucella \) spp., in contrast to other pathogens, do not possess typical virulence factors such as a capsule, flagella, exotoxins, or inducers or host cell apoptosis. They express a lipopolysaccharide (LPS) that, in contrast to LPS from other gram-negative pathogens, is nonendotoxic but is important for the laboratory infections. \( 15 \) Infection can also be transmitted occupationally and occur in farmers, veterinarians, and slaughterhouse personnel after direct contact with infected animals or animal material contaminated with the pathogen. The organism can be isolated from many organs other than the udder and uterus, and the handling of a carcass of an infected animal may represent severe exposure. Brucellosis is also one of the most easily acquired zoonoses in the world.

Immune Mechanisms

Brucellas are able to survive within host leukocytes and may use both neutrophils and macrophages for protection from humoral and cellular bactericidal mechanisms during the periods of hematogenous spread. Immunity against brucellosis is principally mediated by cellular immune responses because it is an intracellular pathogen. \( B. \) abortus is an efficient inducer of type 1 cellular immune responses, and interferon gamma (IFN-\( \gamma \)) is crucial for control of brucellosis. Infections are chronic and often lifelong. The bovine T lymphocyte in brucellosis is in a critical component of host defense based on mononuclear phagocyte activation by IFN-\( \gamma \). The killing of \( Brucella \)-infected mononuclear phagocytes and IFN-\( \gamma \)-mediated activation of mononuclear phagocytes are the major mechanisms of host defenses against brucellosis in cattle.

The antibody response to \( B. \) abortus in cattle consists of an early IgM isotype response, the timing of which depends on the route of exposure, the dose of the bacteria, and the health status of the animal. The IgM response is followed almost immediately by production of IgG1 antibody and later by small amounts of IgG2 and IgA. Most cross-reacting antibody from exposure to bacteria other than \( Brucella \) spp. or environmental antigens consists mainly of IgM. Serologic tests that measure IgM are therefore not desirable, because false-positive results occur. Because IgG1 and IgA antibodies accumulate later after exposure and are usually present in small and inconsistent amounts, the main isotype for serologic testing is IgG1.

Naturally infected animals and those vaccinated as adults with strain 19 remain positive to the serum and other agglutination tests for long periods. The serum of infected cattle contains high levels of IgM, IgG1, IgG2, and IgA isotypes of antibody. Most animals vaccinated between 4 and 8 months of age return to a negative status to the test within a year. All are considered to have a relative immunity to infection. Calves from cows that are positive reactors to the test are passively immunized via the colostrum. The half-life of colostral antibodies to \( B. \) abortus in calves that have received colostrum from either vaccinated noninfected or infected dams is about 22 days. It is possible that some calves remain immune sufficiently long to interfere with vaccination. After vaccination of cattle with strain 19 of the organism, IgM antibodies appear after about 5 days, reaching peak values after 13 days. IgG1 antibodies appear a little later or simultaneously with IgM, and peak values are reached at 28 to 42 days, after which they decline. The same general pattern follows experimental infection with virulent strains and also in chronic field cases, except that IgM antibody declines to low levels and residual activity resides in IgG1 and IgG2 as well as in IgA, which remain at higher levels.

Economic Importance

Losses in animal production caused by this disease can be of major importance, primarily because of decreased milk production in aborting cows. The common sequel of infertility increases the period between lactations, and in an infected herd the average intercalving period may be prolonged by several months. In addition to the loss of milk production, there is the loss of calves and interference with the breeding program. This is of greatest importance in beef herds where the calves represent the sole source of income. A high incidence of temporary and permanent infertility results in heavy culling of valuable cows, and some deaths occur as a result of acute metritis following retention of the placenta.

Zoonotic Implications

According to the Food FAO, the WHO, and OIE, brucellosis is still one of the most important and widespread zoonoses in the world. Of the six \( Brucella \) spp. known to cause human disease (\( B. \) melitensis, \( B. \) abortus, \( B. \) suis, \( B. \) canis, \( B. \) ceti, and \( B. \) pinnipedialis), \( B. \) melitensis is the one with the largest public health impact because it is the most virulent species and has the highest prevalence in small ruminant populations in many areas of the world. \( B. \) abortus and \( B. \) suis serovars 1, 3, and 4 are also important human pathogens; \( B. \) suis serovar 2 and \( B. \) canis are uncommon human pathogens. Most cases in humans are occupational and occur in farmers, veterinarians, and slaughterhouse personnel after direct contact with infected animals or animal material contaminated with the pathogen. The organism can be isolated from many organs other than the udder and uterus, and the handling of a carcass of an infected animal may represent severe exposure. Brucellosis is also one of the most easily acquired laboratory infections. \( 19 \) Infection can also occur after ingestion of raw milk or raw milk products. Officially approved methods of commercial pasteurization render naturally \( Brucella \)-contaminated raw milk safe for consumption.

In endemic regions, the reported incidences of human brucellosis range from less than 0.01 per 100,000 population to more than 200 per 100,000 population. \( 14 \) In the United States, where approximately 100 cases of human brucellosis are reported annually, the incidence rate is less than 0.05 per 100,000 population. \( 14 \) In Europe the highest incidences were reported from Greece (1.09 per 100,000 population), Portugal (0.36 per 100,000 population), and Spain (0.13 per 100,000 population), which together
accounted for 67.7% of all confirmed cases of human brucellosis in member states of the EU in 2012. Of the human cases reported within the EU in 2012 where species information was available 83.9% were caused by *B. melitensis*, 10.1% *B. abortus*, 3.0% *B. suis*, and 3.0% by other *Brucella* spp. The importance of the disease in humans is an important justification for its eradication. The cost-effectiveness to human health and the potential net economic benefits of a nationwide mass vaccination program for livestock over a period of 10 years has been evaluated using Mongolia as the model. If the costs of vaccination of livestock against brucellosis were allocated to all sectors in proportion to the benefits, the intervention would be cost-effective and would result in net economic benefits.

**PATHOGENESIS**

The successful coexistence of *Brucella* spp. with its preferred host is the outcome of coevolutionary relationships and selection pressures, which result in a stalemate where the pathogen has evolved to survive within the biologic system of the host, and the host has evolved innate and acquired immune systems that allow controlled survival of infection by the pathogen, ultimately supporting the survival of the host-pathogen system.

Following ingestion most commonly through the digestive or respiratory tract *Brucella* spp. can invade epithelial cells of the host, allowing infection though intact mucosal surfaces. Once invasion successfully occurs the organism may be phagocytized by host immune cells and may also invade non-phagocytic host cells through a mechanism that is not entirely understood. Following cell invasion the organism is contained in a membrane-bound modified phagosome, the *Brucella*-containing vacuole (BCV), and interferes with intracellular trafficking, preventing fusion of the BCV with lysosome markers and directing the BCV to the rough endoplasmic reticulum, which is highly permissive for intracellular replication of *Brucella*. Invaded polymorphonuclear leukocytes then transport the pathogen to regional lymph nodes, other sites such as the reticuloendothelial system, and organs such as the udder and when present the fetal placenta. In the draining lymph node, *Brucella* infection causes cell lysis and eventual lymph node hemorrhage 2 to 3 weeks following exposure. Because of vascular injury, some of the bacteria enter the bloodstream and subsequent bacteremia occurs, which disseminates the pathogen throughout the body.

*B. abortus* has a predilection for the placenta; udder; testicle; and accessory male sex glands, lymph nodes, joint capsules, and bursae. Erythritol, a substance produced by the fetus and capable of stimulating the growth of *B. abortus*, occurs naturally in greatest concentration in the placental and fetal fluids and is responsible for localization of the infection in these tissues. Invasion of the gravid uterus results in a severe ulcerative endometritis of the intercotyledonal spaces. The allantochorion, fetal fluids, and placental cotyledons are invaded, and the villi are destroyed. The organism has a marked predilection for the ruminant placenta. In acute infections of pregnant cows, up to 85% of the bacteria are in cotyledons, placental membranes, and allantoic fluid. The resulting tissue necrosis of the fetal membranes allows transmission of the bacteria to the fetus. The net effect of chonic and fetal colonization is abortion during the last trimester of pregnancy. The characteristic pneumonia in aborted fetuses is caused by localization of perivascular foci in the interlobular septa of the lung, indicative of hematogenous spread in the fetus rather than aspiration of contaminated fetal fluids. Fetuses inoculated with sufficient numbers of *B. abortus* will abort 7 to 19 days postinoculation. With experimental conjunctival exposure of pregnant heifers with the organism, the numbers of infected animals and the number of tissue samples positive for the organism are increased as fetal age at exposure increases from gestation days less than 127 to more than 157. Abortion occurs principally in the last 3 months of pregnancy, and the incubation period is inversely proportional to the stage of development of the fetus at the time of infection.

Congenital infection can occur in newborn calves as a result of in utero infection, and the infection may persist in a small proportion of calves, which may also be serologically negative until after their first parturition or abortion.

In the adult, nonpregnant cow, localization occurs in the udder, and the uterus, if it becomes gravid, is infected from periodic bacteremic phases originating in the udder. Infected udders are clinically normal, but they are important as a source of reinfection of the uterus, as a source of infection for calves or humans drinking the milk, and because they are the basis for the agglutination tests on milk and whey. Variable disease expression may occur in the male reproductive tract and musculoskeletal system, particularly affecting large joints, of either sex.

**CLINICAL FINDINGS**

**Abortion**

The clinical findings are dependent on the immune status of the herd. In highly susceptible nonvaccinated pregnant cattle, abortion after the 5th month of pregnancy is a typical feature of the disease in cattle. In subsequent pregnancies, the fetus is usually carried to full term, although second or even third abortions may occur in the same cow. Retention of the placenta and metritis are common sequelae to abortion. Mixed infections are usually the cause of the metritis, which may be acute, with sepsicaemia and death following, or chronic, leading to sterility.

The history of the disease in a susceptible herd can usually be traced to the introduction of an infected cow. Less common sources are infected bulls, or horses with fistulous withers. In a susceptible herd, it is common for the infection to spread rapidly and for an abortion “storm” to occur. The storm might last for a year or more, at the end of which time most of the susceptible cows are infected and have aborted and then carry their calves to full term. Retained placenta and metritis could be expected to be common at this time. As the abortion rate subsides, the abortions are largely restricted to first-calf heifers and new additions, because other animals of the herd acquire partial resistance.

In recent years, particularly in areas where vaccination is extensively practiced, an insidious form of the disease may develop, which spreads much more slowly and in which abortion is much less common.

**Orchitis and Epididymitis**

In the bull, orchitis and epididymitis occur occasionally. One or both scrotal sacs may be affected, with acute, painful swelling to twice normal size, although the testes may not be grossly enlarged. The swelling persists for a considerable time, and the testis undergoes liquefaction necrosis and is eventually destroyed. The seminal vesicles may be affected and their enlargement can be detected on rectal palpation. Affected bulls are usually sterile when the orchitis is acute but may regain normal fertility if one testicle is undamaged. Such bulls are potential spreaders of the disease if they are used for artificial insemination.

**Synovitis**

*B. abortus* can often be isolated from the tissues of nonsuppurative synovitis in cattle. Hygromatous swellings, especially of the knees, should be considered with suspicion. Progressive and erosive nonsuppurative arthritis of the stifle joints has occurred in young cattle from brucellosis-free herds that had been vaccinated with strain 19 vaccine. The calves may or may not be serologically positive, but synovial fluid and joint tissue samples contain immunologic evidence of strain 19 *B. abortus* antigenic material. The synovitis has been reproduced by intraarticular injection of the vaccine.

**Fistulous Withers**

In horses, the common association of *B. abortus* is with chronic bursal enlargements of the neck and withers, or with the navicular bursa, causing intermittent lameness, and the organism has been isolated from mares that have aborted. When horses are mixed with infected cattle, a relatively high proportion can become infected and develop a positive reaction to the serum agglutination test.
without showing clinical illness. Some horses appear to suffer a generalized infection with clinical signs including general stiffness, fluctuating temperature, and lethargy.

**CLINICAL PATHOLOGY**

The major objective in the laboratory diagnosis of brucellosis is to identify animals that are infected and potentially shedding the organism and spreading the disease. Most infected animals are identifiable using the standard serologic tests, but latent infection occurs in some animals that are serologically negative. Furthermore, vaccinated animals may be serologically positive and uninfected, and transitory titers occur sporadically in a small percentage of animals, for which there is no clear explanation. These diagnostic problems make control and eradication programs difficult to administer and difficult to explain to animal owners.

The collection and submission of samples to the laboratory must be done with care, and careful attention must be given to recording the identity of the animal and the corresponding sample, which should be uniquely identified. For blood samples, it is recommended that silicone-coated evacuated glass tubes without additives be used to collect the blood sample, because they ensure effective clotting and clot retraction, to provide an easy source of serum without the need for centrifugation. Clotting is also aided by maintaining the sample at 25°C to 37°C for 1 to 2 hours.

Laboratory tests used in the diagnosis of brucellosis include isolation of the organism and serologic tests for the presence of antibodies in blood, milk, whey, vaginal mucus, and seminal plasma. The organism may be present in the cervical mucus, uterine flushings, and udder secretions of experimentally infected cows for up to 36 days after abortion.

**Identification of Brucella spp.**

**Staining**

The appearance of specifically stained smears and the colonial morphology can lead to a presumptive diagnosis of brucellosis. *Brucella* bacteria are not really acid-fast but are resistant to decolonization by weak acids, and the presence of a weakly acid-fast intracellular organism, stained with the Stamp-modified Ziehl–Neelsen method may be suggestive for the presence of *Brucella* spp. in the smear. However, staining has a very limited sensitivity because of the low number of organisms present that may be present in some tissues and body fluids of infected animals. Positive results must be interpreted carefully because of the morphologic similarities of *Brucella* organisms with other pathogens associated with abortion, such as *Coxiella burnetii* or *Chlamydia abortus*. Results, positive or negative, should only be considered presumptive and always need to be confirmed ideally by culture.

**Culture**

The gold standard diagnostic test continues to be based on isolation and characterization of the organism from the organs and lymph nodes of the fetus, the placenta, milk, vaginal mucus, or uterine exudate. Bacteriologic methods detect the organism directly and thus limit the possibility of false-positive results. Isolation of the organism from the udder secretion of a cow is conclusive evidence of infection. Culture methods are reliable and usually definitive. A range of specific culture media are commercially available. A disadvantage is the long time required for definitive identification. Most culture results are positive between the 7th and 21st day and rarely become positive before the 4th day of culture. Incubation for at least 45 days has been advised before declaring a blood sample negative for *Brucella* spp. Furthermore *Brucella* organisms are among the most dangerous bacteria with which to work in terms of the risk of producing laboratory-acquired infections.

**Detection by Polymerase Chain Reaction (PCR)**

The PCR-based assays for *Brucella* spp. have been developed and are simple. PCR has been applied to tissues such as aborted fetuses and associated maternal tissues, blood nasal secretions, semen, and food products such as milk and soft cheeses. *Brucella* spp. can be detected in the milk of naturally infected cattle, sheep, goats, and camels using a PCR assay that is more sensitive than the culture method. A further diagnostic advancement of recent years is the Bruce-ladder PCR, which is a multiplex PCR assay that helps to identify and differentiate several *Brucella* spp., including vaccine strains, in a single step.

**Serologic Tests**

In the absence of a positive culture of *B. abortus*, a presumptive diagnosis is usually made based on the presence of antibodies in serum, milk, whey, vaginal mucus, or seminal plasma.

The antibody response following infection depends on whether or not the animal is pregnant and on the stage of gestation. On average, the agglutinins and complement fixation antibodies become positive 4 weeks following experimental infection during the fourth to sixth months of gestation and not until about 10 weeks if experimental infection occurs 2 months before or after insemination. The serologic diagnosis is considered to be unreliable when applied 2 to 3 weeks before and after abortion or calving.

Any of the currently available serologic tests or combination of tests measures the response of a single animal at one point in time and does not describe the status of the herd. When the tests are used in the recommended sequence and in combination, along with a consideration of accurate epidemiologic data, the limitations of each test can be minimized. None of the tests is absolutely accurate, and there are varying degrees of sensitivity. The result has been the development of a very extensive range of tests, each of which has its own special applicability. The salient features are as follows.

**Agglutination Tests**

**Serum Agglutination Test**

The serum (tube) agglutination test (SAT) or microtiter plate variants of it are some of the traditional standard tests, which are widely used, but are not recognized as prescribed or alternative tests. The main limitations are

- Detect nonspecific antibodies as well as specific antibodies from *B. abortus*
- Infection and vaccination
- During the incubation stage of the disease these tests are often the last to reach diagnostically significant levels
- After abortion caused by *B. abortus*
- They are often the last tests to reach diagnostically significant levels
- In the chronic stage of the disease, the serum agglutinins tend to wane, often becoming negative when the results of some other tests may be positive.

**Rose Bengal Test (Buffered Plate Antigen or Card Test)**

The rose Bengal test (RBT) is a simple, rapid spot-agglutination test using antigen stained with rose Bengal and buffered to low pH. The test detects early infection and can be used as an initial screening test. False-positive reactions are caused by residual antibody activity from vaccination, colloidal antibody in calves, cross-reaction with certain bacteria such as *Yersinia enterocolitica*, and laboratory error. False-negative reactions are observed during early incubation of disease and immediately after abortion. However, the RBT is an excellent test for the large-scale screening of sera. The application of the RBT as a screening test, followed by a confirmatory or complementary test, can markedly increase the proportion of infected cattle that test positive.

For **beef cattle**, screening of herds can be achieved by collecting blood at abattoirs and submitting it to the RBT or tube agglutination test. Reactors are traced back to the herd of origin, and the herd is tested. In heavily infected herds, it is best to remove all cows positive to the RBT even though it is highly sensitive and there will be a small percentage of false-positive cows. In herds where the prevalence of infection is low and where vaccination has been used, this procedure will eliminate too many false-positive cows. In this situation the sera positive to the RBT are submitted to a more definite confirmatory test such as the complement fixation test (CFT), and only those animals reacting to the test are discarded.

---

Chapter 18 ■ Diseases Primarily Affecting the Reproductive System
Complement Fixation Test
The CFT is one of the prescribed tests for international trade and is widely accepted as a confirmatory test. It rarely exhibits nonspecific reactions and is useful in differentiating titers of calfhood vaccination from those caused by infection. The reactions to the CFT recede sooner than those to the serum agglutination test after calfhood vaccination with the strain 19 vaccine. The CFT titers do not wane because the disease becomes chronic and often the CFT reaches diagnostic levels sooner than the serum tube agglutination test following natural infection. In addition, recent technical laboratory advances have allowed much greater speed and accuracy in doing the CFT and it is now considered to be the nearest approach to a definitive test for infection. Nonetheless, because of its complexity the CFT requires good laboratory facilities and skilled laboratory personnel.

Enzyme-Linked Immunosorbent Assays
Two main types of immunosorbent assay have been used: the indirect and competitive formats.

Indirect Enzyme-Linked Immunosorbent Assay
The indirect enzyme-linked immunosorbent assay (iELISA) has been a useful test during an eradication program, after vaccination has ceased; for screening; or as a supplementary test to the CFT. Several variations of the assay using either whole-cell, smooth lipopolysaccharide (sLPS), or O-polysaccharide (OPS) as an antigen have been validated. The iELISA has gained wide acceptance for serologic diagnosis of bovine brucellosis because of its ability to detect antibody of all isolates, unlike the conventional tests. The iELISA can be useful in conjunction with the CFT during the later stages of an eradication program, when it is important to reduce the number of false-negative serologic reactions that contribute to the persistence of problem herds. The iELISA has an excellent sensitivity and specificity but cannot distinguish between the antibody response induced by vaccination with B. abortus strain 19 and natural infection. The iELISA has also been developed and validated for milk, and several different variations of this assay are currently commercially available.

Competitive Enzyme-Linked Immunosorbent Assay
The competitive ELISA (C-ELISA) uses monoclonal antibody specific for one of the epitopes of the Brucella spp., which makes it more specific than assays using cross-reacting antibody. The C-ELISA is thus more specific but less sensitive than the iELISA. It eliminates most but not all reactions caused by cross-reacting organisms and in most but not all cases, eliminates reactions with residual antibody in animals vaccinated with strain 19. The OIE therefore recommends the further investigation of positive reactors with the C-ELISA using appropriate complementary or confirmatory diagnostic tests.

Fluorescence Polarization Assay
This test can be done outside the diagnostic laboratory, allowing for rapid and accurate diagnosis. The fluorescence polarization assay (FPA) can be done almost anywhere using a portable analyzer, which receives power from a laptop computer, using serum, milk, or ethylenediaminetetraacetic acid (EDTA) anticoagulated blood. The FPA technology has been developed and validated for the serologic diagnosis of brucellosis in cattle, pigs, sheep, goats, bison, and cervids. Sufficient cross-reactivity of the common epitopes of B. abortus, B. melitensis, and B. suis has allowed for the use of a single antigen for all species of smooth Brucella and animals. The FPA was initially developed for testing serum; however, the technology has been extended to testing whole blood and milk from individual animals or bulk tank samples pooled from 2000 or fewer animals. The accuracy results of the FPA equals or exceeds those obtained using other serologic tests such as the buffered antigen plate agglutination test, the milk ring test, the CFT, the iELISA, and the C-ELISA. Validation of studies of the FPA and the C-ELISA for the detection of antibodies to B. abortus in cattle sera and comparison to the standard agglutination test, the CFT, and the iELISA, found that the FPA is highly superior. It offers a clear advantage because it is easy to use. Full implementation and acceptance of FPA methods for the diagnosis of brucellosis will necessitate the use of an International Standard Serum panel containing at least a low titer-positive sample and a negative sample.

Brucellin Skin Test
The brucellin skin test presents an alternative immunologic test that can be used to test unvaccinated animals. Tested animals are injected intradermally with 0.1 mL of a standardized brucellin preparation consisting of purified, sLPS-free Brucella antigen. The skin thickness at the injection site is measured with Vernier calipers before and 48 to 72 hours after injection. Skin thickening of at least 1.5 to 2 mm at the injection site are considered a positive reaction. This test is among the most specific brucellosis tests available, provided it is conducted with a purified, standardized antigen preparation; serologically negative unvaccinated animals with a positive reaction to the skin test are therefore considered as infected. Because not all infected animals show a positive reaction the test is not recommended as a stand-alone test for the purpose of international trade.

Sensitivity and Specificity of Serologic Tests
Serologic tests must have high sensitivity to ensure that all true serologic reactors are detected. However, with a high sensitivity, a high rate of false-positive reactions may be expected and hence the need for the use of a confirmatory test to identify false-positive reactors. Confirmatory tests must therefore demonstrate a high level of diagnostic specificity and yet maintain an effective diagnostic sensitivity.

It has been recommended to use a buffered Brucella antigen test, such as the buffered plate antigen test or the RBT as a screening test. Either the CFT or the indirect enzyme immunoassay is appropriate for uses as a confirmatory test in situations requiring a high specificity. The relationships between the quantitative serology and infection status of brucellosis in bison in Yellowstone National Park have been evaluated and found to be similar to those in chronically infected cattle.

Antibodies in Milk
The milk ring test is a satisfactory inexpensive test for the surveillance of dairy herds for brucellosis. A small sample of pooled fresh milk or cream, from no more than 25 cows, is tested and the herd is classified only as suspicious or negative. Final determination of the status of a suspicious herd and each animal in it is accomplished by blood testing. The more frequently a herd is tested with the milk ring test, the more effective the test becomes as a method to detect early infections, preventing serious outbreaks in susceptible herds. At least three tests done annually are now required by some regulatory agencies. The major limitation of the test is the dilution factor, which occurs in large dairy herds where large quantities of milk are stored in bulk tanks. To adjust for this dilution effect, larger sample volumes are used with increasing herd size. Although 1 mL of bulk milk is required for herds with up to 150 head, the use of 2 mL for herds between 150 and 450 head and 3 mL for herds with 450 to 700 head has been advised. False-positive reactions have been observed with cattle vaccinated less than 4 months before testing and in samples containing colostrum or mastitic milk.

The milk iELISA test is a sensitive, specific, and inexpensive method for screening large numbers of individual or bulk milk samples for the antibody to B. abortus. An ELISA using potassium chloride extract of the organism used on bulk tank milk samples of dairy herds was highly specific and is considered as a highly reliable test for monitoring brucellosis control programs. The combined use of an ELISA and PCR on milk samples gives a sensitivity of 100%.

False-Positive Reactors
A major problem in brucellosis eradication programs has been the false-positive animals
Chapter 18 ▪ Diseases Primarily Affecting the Reproductive System

or singleton reactor, which may remain persistently suspicious or positive in a herd that is otherwise considered to be free of brucellosis. It is of some concern because of the unnecessary slaughter of uninfected animals.

Cross-reacting antibodies usually result from exposure to antigen(s) that share antigenic determinants with *Brucella* spp., which are found in a large number of bacteria. The most prominent cross-reaction is with *Yersinia enterocolitica* O:9, which shares the major OPS almost completely with *B. abortus*. Serologic cross-reactions have also been demonstrated between smooth *Brucella* spp. and *Escherichia coli* O116:H21 and *E. coli* O157:H7, *Francisella tularensis*, *Salmonella* serotypes of Kaufman–White group N, *Pseudomonas maltophilia*, *Vibrio cholerae*, and *Y. enterocolitica* serotype O:9. Only rarely will naturally occurring *E. coli* O157:H7 infections cause false-positive reactions with standard serologic tests for bovine brucellosis. The standard serologic tests are unreliable in differentiating between *Y. enterocolitica* and *Brucella*-infected cows, but both the lymphocyte transformation and brucellin skin tests could be used to differentiate them.

Other causes of false positives include a *B. abortus*-infected animal, strain 19 residual vaccination titer, and naturally occurring nonspecific agglutinins, which may occur in some cattle populations. These agglutinins are EDTA labile and can be differentiated from agglutinating antibodies by the addition of EDTA to the diluent used in the standard serum agglutination test. The serologic cross-reactions are of major significance when the prevalence of infection has decreased to a very low level. At this stage it becomes much more important to correctly identify the status of animals reacting to the serologic tests for brucellosis.

The incorrect attribution of such reactions to factors other than *Brucella* infection is likely to result in herd breakdowns and failure to control the disease. On the other hand, the misinterpretation of cross-reactions as evidence of brucellosis results in the imposition of unnecessary restrictions and waste of resources. The problem of serologic cross-reactions has resulted in considerable research and an investigation to find laboratory tests, which will accurately distinguish positive, infected animals from positive, noninfected animals. Differentiation of cross-reacting antibodies can be difficult to achieve, especially in the case of *Y. enterocolitica* O:9 antigen, but immunodiffusion, immunoelectrophoresis, and primary binding tests and cross-absorption procedures are useful. The DNA homology of *B. abortus* strains 19 and 2308 has been examined using restriction enzyme analysis. Strain 19 is the official U.S. Department of Agriculture (USDA)-attenuated *Brucella* vaccine strain for cattle, and strain 2038 is a virulent laboratory-adapted strain that is pathogenic to cattle. The DNA differences between the two strains are small and will require analysis at the DNA sequence level.

The serologic assay of choice for screening samples for antibody to *B. abortus* is the FPA. It is robust, very rapid, and field-adaptable, without subjective results. The C-ELISA is a useful confirmatory assay. The sera from cattle naturally infected with *B. abortus*, vaccinated with *B. abortus* S19, or immunized with *Y. enterocolitica* O:9 or *E. coli* O157:H7, were compared for antibody content to the same bacteria by iELISA, FPA, and C-ELISA. The serologic assay of choice for screening samples for antibody to *B. abortus* is the FPA. Between the two tests, nearly all reactivity to *E. coli* O157:H7 and more than one-half of the sera with antibody to *Y. enterocolitica* O:9 could be eliminated as *Brucella* reactors. These assays, perhaps in combination with a brucellin skin test, may be capable of distinguishing virtually all reactions caused by *Y. enterocolitica* O:9.

**NECROPSY FINDINGS**

The host responses at the organ and tissue levels have been described and are summarized here. Lymph nodes draining the sites of the early stages of infection have marked germinal center hyperplasia and hypertrophy, accompanied by acute neutrophilic and eosinophilic lymphadenitis. In the later stages of the infection, lymph nodes draining mammary gland, head, and reproductive tract develop chronic granulomatous lymphadenitis, which is usually associated with cortical and paracortical T-cell–dependent lymphoid depletion, germinal center expansion, and deep histiocytic expansion. The spleen may develop lymphoid hyperplasia and histiocytic and plasmacytic expansion in the germinal centers, and the mammary gland usually has a pronounced interstitial lymphoplasmacytic mastitis. In the uterus, there is usually an endometritis, fibrous mural lymphocytic metritis, and caruncular necrotizing vasculitis, whereas the placenta is colonized with *B. abortus* and has extensive desquamation of fetal chorioallantoic trophoblasts with subsequent hematogenous spread to villous trophoblastic epithelium, and necrotizing fibrinopurulent cotyledonary placental lesions of the placental arcades accompanied by granulation and intercotyledonary inflammation exudation. The placenta is usually edematous. There may be leathery plaques on the external surface of the chorion, and there is necrosis of the cotyledons. The key microscopic feature of this inflamed chorioallantois is the presence of intracytoplasmic coccobacilli within chorionic trophoblasts. The use of modified Ziehl–Neelsen stains on impression smears from fresh placentas can provide a rapid presumptive diagnosis. The fetal lesions consist of marked fibrinopurulent necrotizing bronchopneumonia; mononuclear and neutrophilic alveolitis; thromboembolic necrotizing arthritis and lymphangitis; fibrinopurulent pleuritis; and granulomata of the liver, spleen, kidney, and lymph nodes. In fetuses naturally and experimentally infected with *B. abortus*, the tissue changes include lymphoid hyperplasia in multiple lymph nodes, lymphoid depletion in the thymic cortex, adrenal cortical hyperplasia, and disseminated inflammatory foci composed mainly of large mononuclear leukocytes.

The affected joints usually develop a fibrinous and granulomatous synovitis with proliferative villous projection formation, proliferative tendovaginitis with lymphoplasmacytic nodule formation, and arthritis with articular erosions, which may be associated with supplicative, granulomatous bursitis. In the testes there are unilateral or bilateral visceral to parietal tunica adhesions, interstitial lymphocyte orchitis with seminiferous tubular degeneration, necrotizing intratubular orchitis, and acute fibrinopurulent periorchitis with infarction. The ampulla may have a unilateral or bilateral granulomatous epididymitis with focally necrotic purulent and calcified sperm granuloma, and the seminal vesicles have unilateral or bilateral necrotizing fibrinopurulent seminal vesiculitis and interstitial lymphocytic, plasmaocyti seminai vesiculitis with necrosis.

The distribution of *B. abortus* in experimentally and naturally infected cattle has been examined. In experimentally infected pregnant cows, the most frequently infected specimen was the mammary lymph node; the organism could also be found in other lymph nodes, uterine caruncles, cotyledons, or fetal tissues. In naturally infected steers, the most frequently infected specimen was the mandibular lymph node. In bulls, the most frequently infected tissues were the mandibular, caudal superficial cervical, subiliac, and scrotal lymph nodes.

The lesions in *Brucella*-positive aborted fetuses and placentas in bison are similar to those in experimental infections of *B. abortus* in bison and cattle. Both *B. abortus* biovar 1 and *B. abortus* biovar 2 were isolated from specimens collected from aborted bison fetuses or stillborn calves and their placentas. The infection can also be associated with death in calves at least 2 weeks of age.

**Samples for Confirmation of Diagnosis**

- **Bacteriology**: maternal caruncle; placenta, fetal stomach content, lung (culture, has special growth requirements; cytology, Stamp’s or Koster’s stain on placental smears)
- **Histology**: fixed placenta, lung, spleen, brain, liver, kidney; maternal caruncle (light microscopy, immunohistochemistry)

Note the zoonotic potential of this organism when handling carcasses and submitting specimens.
DIFFERENTIAL DIAGNOSIS

The diagnosis of the cause of abortion in a single animal or in a group of cattle is difficult because of the multiplicity of causes that may be involved. When an abortion problem is under investigation, a systematic approach should be used. This includes a complete laboratory evaluation and follow-up inquiries into each herd.

The following procedure is recommended:

- Ascertain the age of the fetus by inspection and from the breeding records.
- Take blood samples for serologic tests for brucellosis and leptospirosis.
- Examine uterine fluids and the contents of the fetal abomasum at the earliest opportunity for trichomonads, and subsequently by cultural methods for B. abortus, Campylobacter fetus, trichomonads, Listeria spp., and fungi.
- Supplement these tests by examination of urine for leptospires, and of the placenta or uterine fluid for bacteria and fungi, especially if the fetus is not available.
- Examine placenta fixed in formalin for evidence of placentitis. It is most important that all examinations are done in all cases because coincident infections with more than one agent are not uncommon.

In the early stages of the investigation, the herd history may be of value in suggesting the possible etiologic agent. For example, in brucellosis, abortion at 6 months or later is the major complaint, whereas in trichomoniasis and vibriosis, failure to conceive and prolongation of the diestrum period is the usual history.

Of special interest is epizootic bovine abortion, which is a major disease of rangeland cattle in the western United States. A spirochete has been isolated from the soft tick Ornithodoros coraisceus and from the blood of fetuses with lesions of epizootic bovine abortion. The disease occurs at a very high level of incidence but only in cattle introduced to a certain area; resident cattle are usually unaffected. Cattle returned to the area each winter are unaffected after the first abortion. The cows are unaffected systemically. Aborted fetuses show characteristic multiple petechiae in the skin, conjunctiva, and mucosa; enlargement of lymph nodes; anasarca; and nodular involvement of the liver.

In most countries where brucellosis is well under control and artificial insemination limits the spread of vibriosis and trichomoniasis, leptospirosis may be the most common cause of abortion in cattle.

However, surveys in such countries reveal that in about two-thirds of the abortions that occur no causative agent is detectable with routine laboratory techniques. In only 35% of cases was the cause determined, and brucellosis accounted for less than 1% of the total. In an Australian experience, the cause of abortion was determined in only 37% of cases in spite of the submission of the fetus, placenta, and maternal serum. The general procedures for submission of specimens to the laboratory and laboratory methods are available.

Bulls

Infected bulls may be serologically positive or negative, and their semen may be culturally positive or negative, but the organism may be isolated at slaughter. Clinical examination may reveal the presence of epididymitis, orchitis, seminal vesiculitis, and ampullitis. All bulls from known infected herds should therefore be considered as suspicious, regardless of their serologic status, and not be used for artificial insemination.

TREATMENT

Treatment is unsuccessful because of the intracellular sequestration of the organisms in lymph nodes, the mammary gland, and reproductive organs. *Brucella* spp. are facultative intracellular bacteria that can survive and multiply within the cells of the macrophage system. Treatment failures are considered to be caused by the inability of the drug to penetrate the cell membrane barrier instead of the development of antimicrobial resistance.

CONTROL AND ERADICATION

Most countries with brucellosis have programs designed to control and ultimately eradicate the infection in cattle to reduce economic losses and protect the public from the disease. These programs usually have several components, and to ensure effectiveness each component needs to be scientifically sound and accepted by all concerned. The major components of a control and eradication program are as follows.

Test and Reduction of Reservoir of Infection

All breeding cattle in the herd are tested, and those that are positive are culled and sent for slaughter. This removes infected cows from the herd and reduces exposure and transmission within the herd. Of particular importance is the detection and removal of infected cows before parturition.

Quarantine

This is a period of time during which cattle movement is restricted and the cattle are tested. This will prevent interherd transmission by infected cattle, especially those that are test negative and incubating the disease. The quarantine period should be sufficiently long that all cattle have had sufficient time to develop brucellosis and ensure that the remaining cattle will not be a source for interherd transmission. The time will usually range from 120 days to 1 year, or until all breeding animals have completed a gestation without test evidence of infection.

Depopulation

Depopulation is slaughter of all cattle in a herd when all animals have been exposed and are capable of becoming infected and acting as a source of new infection.

Vaccination

Properly vaccinated cattle are less likely to be infected and, therefore, are less likely to shed field strains of the organism. Vaccination strategies will be discussed in more detail below.

Education

All participants in a program must understand and adopt the scientific basis for the program. This includes livestock producers, veterinarians, and regulatory officials.

Guidelines

To be successful, any program needs guidelines and policies, which must be followed and modified to meet the needs of certain areas or herds.

Apart from the question of human exposure to infection, the cost and economic benefits of an eradication program must be assessed against the costs and benefits from a vaccination control program. Certain basic considerations apply to all programs aimed at the eradication of brucellosis.

- The control programs indigenous to any given area must receive primary recognition, and any plan or plans must be adapted to that area.
- Cooperation at all levels of government from local to the national is essential for the success of a program. This is attained only after an intensive program of education has been performed. The individual owner of an infected herd must recognize the problem of brucellosis and express a willingness to cooperate. Experience has shown that the owner must be impressed with the hazards of the disease for human health and with the economic losses in the herd.
- A reliable and uniform diagnostic procedure must be generally available.
- If disease is detected in a herd, established procedures should be available for handling the disease. If immunization is to be used, a standardized and effective vaccine must be readily available. The disposal of infected animals may create a serious economic threat for the owner and the possibilities of financial compensation must be explored.
- Finally, and of major importance, the movement of animals from one area to another must be controlled at a high level, because a rigid eradication program in one area may be nullified by neglect in a neighboring area.

Sufficient information exists about bovine brucellosis that it can be eradicated. The
disease was considered to have been eradicated from Great Britain in 1981; in 1985, having met certain European Community criteria for national surveillance and with over 99.8% of the cattle herds free from brucellosis, all herds within the country not under restrictions were designated as being officially brucellosis free for trade purposes. However, small foci of infection persisted, and following the prohibition of the use of Brucella vaccines the national herd was becoming fully susceptible to brucellosis. This was followed by outbreaks of brucellosis in southwest England from 1984 to 1986. The movement of cattle through premises owned by dealers who specialized in the purchase and sale of newly calved cattle was a significant epidemiologic feature of these herd breakdowns.

Control by Vaccination
Because of the serious economic and medical consequences of brucellosis, efforts have been made to prevent the infection through the use of vaccines. Historically brucellosis vaccines were composed of attenuated strains of B. abortus and B. melitensis. These vaccines were shown to be effective in reducing pathogen transmission and production loss, but were less effective in preventing infection. Another inconvenience of these whole-cell vaccines was that they interfere with diagnostic assays detecting antibody against the O-side chain of the Brucella LPS.12 Currently vaccines used to protect livestock against infection with B. abortus contain one of three attenuated live strains of B. abortus: strain 19, RB51, and strain 82.

Brucella abortus Strain 19 Vaccine
Vaccines containing the live B. abortus strain 19 are the most widely used vaccines to prevent bovine brucellosis and are considered the reference vaccines to which any other vaccine is compared.7 The vaccine protects uninfected animals living in a contaminated environment, enabling infected animals to be disposed of gradually. This overcomes the main disadvantage of the test and disposal method of eradication, in which infected animals must be discarded immediately to avoid spread of infection. B. abortus strain 19 has a low virulence and is incapable of causing abortion except in a proportion of cows vaccinated in late pregnancy. Strain 19 is a smooth B. abortus strain expressing the O-antigen on its LPS. Antibody produced in response to vaccination will interfere with diagnostic assays identifying this antigen, which is a major problem with the use of these vaccines. Another weakness of the vaccines is that it cannot completely prevent infection.18

Strain 19 vaccines are normally administered to female calves between 3 and 8 months old as a single subcutaneous dose of 5 to 8 × 10⁶ organisms (calfhood vaccination). There is no significant difference between the immunity conferred at 4 and at 8 months of age. Calves vaccinated with strain 19 at 2 months of age have resistance comparable to those vaccinated at 4 to 8 months of age. However, generally, calves under 75 days of age are immunologically immature in response to strain 19 vaccine. Vaccination of calves with a single dose at 3 to 5 weeks of age does not provide protection compared with vaccination at 5 months of age.

In calves vaccinated between the recommended ages, the serum agglutination test returns to negative by the time the animals are of breeding age, except in a small percentage (6%) of cases. The LPS with an O-chain on B. abortus strain 19 explains the appearance and persistence of antibodies in serum following vaccination. These antibodies are detectable in the serologic assays used for the diagnosis of brucellosis and are the major problem with strain 19 vaccination, because they prevent easy differentiation of vaccinated from infected cattle. The appearance and persistence of these antibodies depends on age, dose, and route of vaccination. This situation makes the continued use of the vaccine incompatible with simultaneous application of test and slaughter procedures for the control of brucellosis.

In brucellosis-free herds where heifers are vaccinated between 4 and 9.5 months of age, positive titers may persist for up to 18 months if they are tested with screening tests such as the RBT. This supports the official policy in some countries not to test vaccinated heifers before 18 months of age and to retest positive cases with the CFT. In most control programs, vaccination is usually permitted up to 12 months of age, but the proportion of persistent postvaccinal serum and whey reactions increases with increasing age of the vaccinates. Such persistent reactors may have to be culled in an eradication program unless the reaction can be proved to be the result of vaccination and not due to virulent infection.

Vaccination of adult cattle is usually not permitted if an eradication program is contemplated, but it may be of value in reducing the effects of an abortion storm. Under specific circumstances vaccination of adult cattle with a reduced single subcutaneous dose of 3 × 10⁷ to 3 × 10⁸ viable organisms can be used but will result in persistent antibody titers in some animals. Furthermore, the risk of abortion when vaccinating pregnant animals and the risk of excretion of the vaccine strain in milk has been reported.1 An alternative vaccination protocol for adult cattle consists in the single or repeated subconjunctival administration of a dose of 5 × 10⁸ living organisms. This latter protocol was reported to reduce the risk of abortion and shedding in milk while providing similar protection.2

Vaccination of bulls is of no value in protecting them against infection and has resulted in the development of orchitis and the presence of B. abortus strain 19 in the semen. For these reasons the vaccination of bulls is discouraged.

Efficiency of Brucella abortus Strain 19 Vaccine
Calfhood Vaccination. This can be assessed by its effect on both the incidence of abortion and the prevalence of infection as determined by testing. Field tests show a marked reduction in the number of abortions that occur, although the increased resistance to infection, as indicated by the presence of B. abortus in milk, may be less marked. Vaccinated animals have a high degree of protection against abortion and 65% to 75% are resistant to most kinds of exposure. The remaining 25% to 35% of vaccinated animals may become infected but usually do not abort. Experimentally, 25% of cattle vaccinated with strain 19 will become infected following challenge. Vaccinated animals continually exposed to virulent infection may eventually become infected and act as carriers without showing clinical evidence of the disease.

In summary, vaccination with a single dose of B. abortus strain 19 vaccine given subcutaneously at 3 to 8 months of age confers adequate immunity against abortion for five or more subsequent lactations under conditions of field exposure. Multiple or late vaccinations have no appreciable advantage and increase the incidence of postvaccinal positive agglutination reactions. When breakdowns occur, they are caused by excessive exposure to infection and not by enhanced virulence of the organism. In herds quarantined for brucellosis, calfhood vaccination reduces reactor rates, duration of quarantine, and the number of herd tests.

Adult Vaccination. Vaccination of adult cows with strain 19 vaccine is highly successful in reducing the number of infected cows in large dairy herds in which it is impossible to institute management procedures for the ideal control of brucellosis.

The vaccination of adult cattle with a reduced dose of vaccine is efficacious and results in an agglutinin response that declines more rapidly after vaccination than when the full dose is used. The reduced dose also provides protection comparable to the standard dose. Vaccination eliminates clinical disease and reduces exposure of infection to susceptible cattle. The reduction of infected adult cattle may vary from 60% to 80% in 6 to 9 months following vaccination. The CFT becomes negative sooner than the standard tube agglutination test following vaccination and can be used to distinguish postvaccine titers from culture-positive cows. The use of reduced doses of strain 19 vaccine in adult cows will also help to eliminate the problem of postvaccine titers.
The protection provided by subcutaneous and conjunctival routes of vaccination is the same but the subcutaneous route may result in a persistent serologic response, which requires complement fixation testing and milk culture to identify infected animals.

The principal advantages of adult vaccination include the following:

- An effective method of control of abortion
- Reduction in the reactor losses in herds
- Reduction of the number of tests required to eliminate brucellosis from infected herds

The major disadvantages of adult vaccination are:

- Residual vaccine titers
- Persistent positive milk ring test
- Persistent strain 19 infection in a small percentage of adult vaccines
- The stigma attached to adult vaccines, which identifies them with infected herds, even though brucellosis has been eliminated and the herd released from quarantine

*B. abortus* strain 19 has been recovered from the supramammary lymph nodes of cattle at slaughter that were vaccinated with a low dose of the vaccine 9 to 12 months previously and had persistent titers to the CFT. The stage of gestation affects the immune responses of cattle to strain 19 vaccination. Cattle that are late in the first or early in the second trimester of gestation (84 to 135 days) at the time of administration of a low dose of strain 19 are at greater risk of being positive by official tests for brucellosis. Vaccination of cattle during the third trimester with a low dose of the vaccine is not as efficacious as when performed earlier. Although reduced-dose strain 19 vaccination is a possible alternative to the total depopulation of problem herds, its use during pregnancy should be avoided because of the risk of abortion and positive serologic titers and positive bulk milk ring tests.

The results expected following adult vaccination depend on the disease situation. In herds vaccinated in the acute phase of the disease, abortion may continue for 60 to 90 days but the incidence begins to decline by 45 to 60 days. A large number of serologic reactors will be present for the first 120 days following vaccination, and testing is usually not done for the first 60 days. The rate of reactors declines rapidly after 120 days and with good infected herd management most adult vaccinated herds can be free of brucellosis 18 to 24 months following vaccination.

The prevalence of *B. abortus* strain 19 infection in adult vaccinated cattle is low and is often not permanent. The prevalence is lower among cattle given the reduced dose of the vaccine subcutaneously. Bacteriologic examination of the milk and serologic examination of the infected cattle are necessary to identify strain 19 infected cattle, which can be retained for milk production because the infections are temporary.

**Adult vaccination**, even with a low dose, should not be used in uninfected herds because of persistent titers, which may last for more than 12 months in up to 15% of vaccinated animals, and because of the potential for abortion. The illegal or unintentional use of the standard dose of strain 19 vaccine in adult cattle will result in a sudden steep antibody titer response in the CFT, which declines in 6 to 11 months. In herds where adult vaccination with a reduced dose of vaccine is used, blood samples should be collected about 4 months after vaccination and subsequently at intervals of 2 months. Those positive to the CFT should be culled. In one study of three large dairy herds in California, the CFT at 2 and 4 months after vaccination was used to identify and cull pregnant reactor cows that were at risk of aborting or calving. The prevention of parturition of infected cows is an effective management technique.

**Systemic Reactions to Vaccination With Strain 19**

These occur rarely in both calves and adults, and may be more severe in Jersey calves than in other breeds. A local swelling occurs, particularly in adult cattle, and there may be a severe systemic reaction manifested by high fever (40.5–42°C; 105–108°F) lasting for 2 to 3 days, anorexia, listlessness, and a temporary drop in milk production. An occasional animal goes completely dry. The swellings are sterile and do not rupture, but a solid, fibrous mass may persist for many months.

Deaths within 48 hours of vaccination have been recorded in calves after the use of lyophilized vaccine.

*B. abortus* strain 19 vaccine has been associated with lameness in young cattle with synovitis following vaccination. Experimentally, the intraarticular injection of the vaccine strain can produce synovitis similar to that which occurs following vaccination.

Septicemia due to *B. abortus* may cause some deaths but in most cases the reaction is anaphylactic, and vaccinated calves should be kept under close observation. Immediate treatment with epinephrine hydrochloride (1 mL of 1:1000 solution subcutaneously) or antihistamine drugs is recommended and is effective provided it can be administered in time.

Cows in advanced pregnancy may abort if vaccinated, but the abortion rate is only about 1%; although *B. abortus* strain 19 organisms can be recovered from the fetus and placenta, their virulence is unchanged and they do not cause further spread of infection. Vaccination with strain 19 does not have a deleterious effect on the subsequent conception rate.

**Brucella abortus** Strain RB51 Vaccine

*Brucella abortus* strain RB51 (SRB51) is a live, stable, rough mutant of *B. abortus* strain 2308 that lacks much of the LPS O-side chain, therefore, it does not interfere with serologic surveillance tests. Since 1996 vaccines containing SRB51 have become the official vaccines for prevention of brucellosis in several countries. The results of studies comparing the efficacy of SRB51 and strain 19 vaccines in the literature are inconsistent. Generally, SRB51 vaccines are administered subcutaneously to female calves between 4 and 12 months old with a dose of 1 to 3.4 × 10⁹ viable organisms. Heifer calves vaccinated at 3 months, 5 months, or 7 months of age with the SRB51 vaccine were protected when challenged against infection and abortion during their first pregnancy. None of the heifers developed antibodies that reacted in the standard agglutination test. A reduced dose of 1 × 10⁶ viable organisms administered as calfhood vaccine does not protect against *B. abortus* infection.

Vaccination of cattle over 12 months of age may be permitted under some circumstances and is performed by subcutaneous administration of a single dose of 1 to 3 × 10⁹ viable organisms. The use of SRB51 vaccines in pregnant cows is discouraged. The strain RB51 has a tropism for the bovine placental trophoblast and has been associated with placentitis and abortion under field conditions. A reduced dose of an SRB51 vaccine containing 1 × 10⁶ viable organisms given to pregnant cattle was protective against infection with *Brucella abortus* without causing placentitis or abortion but resulted in shedding of the vaccine strain in a significant proportion of vaccinated animals. Vaccination of mature sexually intact bulls and heifers with a standard calfhood dose of SRB51 is not associated with shedding or colonization in tissues, and does not appear to cause any reproductive problems when administered to sexually mature cattle. Use of the vaccine in cattle already vaccinated with strain 19 vaccine will not cause positive responses on confirmation tests and does not interfere with brucellosis surveillance.

Studies with strain RB51 vaccine indicate that it is as efficacious as *B. abortus* strain 19 vaccine but is much less abortigenic in cattle. It does not produce any clinical signs of disease after vaccination and does not produce a local vaccination reaction at the injection site. The organism is cleared from the bloodstream within 3 days and is not present in nasal secretions, saliva, or urine. Immunosuppression does not cause recrudescence, and the organism is not spread from vaccinated to nonvaccinated cattle. The vaccine is safe in all cattle over 3 months of age.

In the United States, strain RB51 vaccine was licensed by the USDA’s Animal and Plant Health Inspection Service (APHIS) in 1996 for use in cattle and was approved for use in
chapter 18 - diseases primarily affecting the reproductive system

the cooperative state–federal brucellosis eradication program. strain rb51 vaccine must be administered by an accredited veterinarian or by a state or federal animal health official. calves must be vaccinated with the calf dose (1-3.4 × 10⁸ organisms) between 4 and 12 months of age. only animals in high-risk areas should be vaccinated over 12 months of age.

vaccinates must be identified with the standard metal vaccination eartag and a vaccination tattoo. the tattoo will be the same as the tattoo for b. abortus strain 19 vaccination except the first digit for the quarter of the year will be replaced with an r to distinguish animals vaccinated with rb51 from those vaccinated with strain 19. recording and reporting are the same as with strain 19 vaccine. the diagnosis requires special diagnostic tests that are not routinely available in most hospitals. both strains are sensitive to a range of antimicrobials. physicians deciding to initiate a metaphylactic treatment in a human patient exposed to the rb51 vaccine strain must be advised that this strain is resistant to rifampin, one of the antimicrobials of choice for the treatment of human brucellosis.

brucella vaccines in wildlife

a reservoir of b. abortus-infected bison in the greater yellowstone area in the united states is an obstacle in the effort to eradicate brucellosis from the united states and a source of potential reinfection for livestock in the states of wyoming, idaho, and montana. the free-ranging and infected bison in the area migrate from public land on to private lands and may come into contact with cattle. brucella-induced abortions in bison have occurred under experimental and field conditions, and infected bison can transmit brucellosis under range conditions. wild and free-ranging bison in parts of western canada have also been shown to be infected with bovine brucellosis. therefore a safe and effective vaccine suitable for delivery to free-ranging bison in the greater yellowstone area and in canada is considered useful in reducing the risk of transmission and an aid in the prevention and control of the disease.

brucella abortus strain 19 in bison

the use of strain 19 vaccine has been evaluated in pregnant bison and 10-month-old calves, and the results have been unsatisfactory. in adult bison, strain 19 was found to be highly abortigenic, and animals vaccinated as calves were not protected from infection after experimental inoculation in later life.¹⁸

brucella abortus strain rb51 in bison

the vaccine is safe for vaccination in herds of naive and previously exposed bison calves, young growing bison, adult males, and adult pregnant and nonpregnant females. fetal lesions do not appear to be significant with bison cows vaccinated with rb51 in early gestation, but placentitis and abortion have occurred incidentally in advanced stages of pregnancy. limited data from efficacy studies indicate that booster vaccination with strain rb51 vaccines may increase the protection after experimental challenge.¹⁸

calfhood vaccination of bison with srb51 vaccines is efficacious in protecting against intramammary, intraterine, and fetal infection following exposure to a virulent strain of b. abortus during pregnancy. however, these vaccines appear to be less effective in bison than in cattle in protecting from experimental infection. limited data from efficacy studies indicate that booster vaccination with strain rb51 vaccines may increase the protection after experimental challenge.¹⁸ calfhood vaccination with strain rb51 would be beneficial in a program to reduce the prevalence of b. abortus field strains in american bison. as with cattle, srb51 calfhood vaccination provides a method to prevent transmission and reduce the numbers of susceptible individuals in a bison herd without interfering with serologic identification of brucella-infected animals. brucellosis management programs in bison and elk are unlikely to be successful if capture and hand vaccination is necessary. the effect of hand vaccination versus ballistic vaccination for vaccination of bison and elk on the immunologic responses to srb51 has been evaluated. ballistic delivery may require a greater dose of srb51 to induce cell-mediated immune responses in bison that are comparable to those induced by hand injection.

brucella abortus strain rb51 in elk (cervus elaphus canadensis)

several studies conducted in elk using strain 19 and srb51 vaccines have yielded disappointing results with poor or no protection against experimental infection. neither single nor repeated doses provided significant protection against b. abortus-induced abortion. following vaccination, elk remain bacteremic for a prolonged period of time, rapidly develop high antibody titers while the cellular immune response is poor or lacking.¹⁸

control programs on a herd basis

the following recommendations are based on the need for flexibility depending on the level of infection that exists and the susceptibility of the herd and the disease regulations in effect at the time.

during an abortion storm

test and disposal of reactors may be unsatisfactory during an outbreak because spread occurs faster than eradication is possible. vaccination of all nonreactors is recommended in some countries or, if testing is impracticable, vaccination of all cattle. it is preferable to retest the herd before the second vaccination and to cull cows with a threefold rise in agglutination titer.

heavily infected herds in which few abortions are occurring

does not present an urgent problem because a degree of herd resistance has been reached. all calves should be vaccinated immediately, and positive reactors among the remainder should be culled as soon as possible. periodic milk ring tests (preferably at 2-month, and no more than 3-month intervals) on individual cows are supplemented by complement fixation and culture tests.

lightly infected herds

describe a special problem. if they are situated in an area where infection is likely to be introduced, calfhood vaccination should be implemented and positive reactors immediately culled. if eradication is the goal in the area, culling of reactors will suffice, but special market demands for vaccinated cattle may require a calfhood vaccination policy. when a herd is declared free of brucellosis on the basis of serum agglutination tests, its status can be maintained by introducing only negative-reacting animals from brucellosis-free herds and annual blood testing. in areas where dairying predominates, semiannual testing of milk may be substituted for blood testing.

in all of the previously mentioned programs, the careful laboratory examination of all aborted fetuses is an important and necessary corollary to routine testing. there are many difficulties achieving control and eventual eradication on a herd basis. these relate mainly to the failure of owners to realize the highly infectious nature of the disease and to cooperate fully in the details of the program. particularly, they may fail to recognize the recently calved cow as the principal source of infection. in a herd control program, such cows should be isolated at calving and blood tested at 14 days, because false-negative reactions are not uncommon before that time.

hygienic measures

describe the isolation or disposal of infected animals; disposal of aborted fetuses, placentas, and uterine discharges; and disinfection of contaminated areas. it is particularly important that infected cows be isolated at parturition. all cattle, horses, and pigs brought on to the farm should be tested, isolated for 30 days, and retested. introduced cows that are in advanced pregnancy should be kept in isolation until after parturition, because occasional infected cows may not show a positive serum reaction until after calving or abortion. chlorhexidine gluconate is an effective antiseptic against b. abortus and is recommended for washing the arms and hands of animal attendants and veterinarians who come into contact with contaminated tissues and materials.

Vaccines in Wildlife

Brucella abortus Strain 19 in Elk

Several studies conducted in elk using strain 19 and SRB51 vaccines have yielded disappointing results with poor or no protection against experimental infection. Neither single nor repeated doses provided significant protection against B. abortus-induced abortion. Following vaccination, elk remain bacteremic for a prolonged period of time, rapidly develop high antibody titers while the cellular immune response is poor or lacking.¹⁸

Control Programs on a Herd Basis

The following recommendations are based on the need for flexibility depending on the level of infection that exists and the susceptibility of the herd and the disease regulations in effect at the time.

During an Abortion Storm

Test and disposal of reactors may be unsatisfactory during an outbreak because spread occurs faster than eradication is possible. Vaccination of all nonreactors is recommended in some countries or, if testing is impracticable, vaccination of all cattle. It is preferable to retest the herd before the second vaccination and to cull cows with a threefold rise in agglutination titer.

Heavily Infected Herds in Which Few Abortions Are Occurring

These do not present an urgent problem because a degree of herd resistance has been reached. All calves should be vaccinated immediately, and positive reactors among the remainder should be culled as soon as possible. Periodic milk ring tests (preferably at 2-month, and no more than 3-month intervals) on individual cows are supplemented by complement fixation and culture tests.

Lightly Infected Herds

These present a special problem. If they are situated in an area where infection is likely to be introduced, calfhood vaccination should be implemented and positive reactors immediately culled. If eradication is the goal in the area, culling of reactors will suffice, but special market demands for vaccinated cattle may require a calfhood vaccination policy. When a herd is declared free of brucellosis on the basis of serum agglutination tests, its status can be maintained by introducing only negative-reacting animals from brucellosis-free herds and annual blood testing. In areas where dairying predominates, semiannual testing of milk may be substituted for blood testing.

In all of the previously mentioned programs, the careful laboratory examination of all aborted fetuses is an important and necessary corollary to routine testing. There are many difficulties achieving control and eventual eradication on a herd basis. These relate mainly to the failure of owners to realize the highly infectious nature of the disease and to cooperate fully in the details of the program. Particularly, they may fail to recognize the recently calved cow as the principal source of infection. In a herd control program, such cows should be isolated at calving and blood tested at 14 days, because false-negative reactions are not uncommon before that time.

Hygienic Measures

These include the isolation or disposal of infected animals; disposal of aborted fetuses, placentas, and uterine discharges; and disinfection of contaminated areas. It is particularly important that infected cows be isolated at parturition. All cattle, horses, and pigs brought on to the farm should be tested, isolated for 30 days, and retested. Introduced cows that are in advanced pregnancy should be kept in isolation until after parturition, because occasional infected cows may not show a positive serum reaction until after calving or abortion. Chlorhexidine gluconate is an effective antiseptic against B. abortus and is recommended for washing the arms and hands of animal attendants and veterinarians who come into contact with contaminated tissues and materials.
Eradication on an Area Basis by Test and Slaughter and Cessation of Calfhood Vaccination

Following a successful calfhood vaccination program, eradication on an area basis can be considered when the level of infection is below about 4% of the cattle population. Brucellosis control areas must be established and testing and disposal of reactors and their calves at foot is performed. Financial compensation is paid for disposal of reactors. Infected herds are quarantined and retested at intervals until negative; in heavily infected herds complete depopulation is often necessary. Brucellosis-free areas are established when the level of infection is sufficiently low, and the movement of cattle between areas is controlled to avoid the spread of infection.

Farms with a low incidence may find it possible to engage in an eradication program immediately provided the incidence on surrounding farms is low. Breakdowns may occur if there are accidental introductions from nearby farms, and in these circumstances it is hazardous to have a herd that is not completely vaccinated. When the area incidence is low enough (about 5%) that replacements can be found within the area or adjoining free areas, and immediate culling of reactors can be performed without crippling financial loss, compulsory eradication by testing and disposal of reactors for meat purposes can be instituted. Compensation for culled animals should be provided to encourage full participation in the program.

The work of testing can be reduced by using screening tests to select herds for more intensive epidemiologic and laboratory investigation. In dairy herds, the milk ring test conducted on bulk milk samples is useful. In beef herds, the favored procedure is the collection of blood from drafts of cattle at the abattoir and use of the RBT. The same technique has also been used to screen shipments of beef destined for countries with an aversion to meat infected with *B. abortus*. An additional means of reducing labor costs in an eradication program is the use of automated laboratory systems such as the one available for the RBT and the one based on agglutination and CFT. An educational program to promote herd owners to voluntarily submit all aborted fetuses to a laboratory for bacteriologic examination is also deemed necessary in any eradication scheme. When an area or country is declared free, testing of all or part of the population needs to be performed only at intervals of 2 to 3 years, although regular testing of bulk milk samples (milk ring test) and of culled beef cows in abattoirs and examination of fetuses should be maintained as checks on the eradication status. In all eradication programs, some problem herds will be encountered in which testing and disposal do not eliminate the infection. Usually about 5% of such herds are encountered and are best handled by a “problem herd” program. Fifty percent of these herds have difficulty because of failure to follow directions. The other half usually contain infected animals that do not respond to standard tests. Supplementary bacteriologic and serologic tests as set out previously may occasionally help these spreader animals to be identified and the disease to be eradicated.

United States

Efforts to eradicate brucellosis associated with *B. abortus* in the United States began in 1934 as an economic recovery program to reduce the cattle population because of the Great Depression. Brucellosis was considered the most significant livestock disease at that time, with a reactor rate of 11.5%. In 1954, a cooperative federal and state program was launched based on calfhood vaccination and test and slaughter with compensation. Two very effective surveillance programs for detecting brucellosis were the market cattle testing and milk ring testing of dairy herds. On July 10, 2009, all 50 states, Puerto Rico, and the U.S. Virgin Islands were officially classified as class free for bovine brucellosis.19 The number of human cases of brucellosis declined with the decline in number of cases in animals. As of 2013, about 100 human cases per year are reported of which most cases are associated with consumption of unpasteurized milk and milk products of goat origin infected with *B. melitensis*.

Bison and elk in the Greater Yellowstone area are the last known remaining reservoir of *B. abortus* in the United States. Control of brucellosis in these species on public lands requires special consideration to preserve the largest wild, free-ranging population of bison in the United States. Vaccination trials are under way.

The primary surveillance methods for testing eligible cattle in the United States are the *market cattle testing* program in the beef industry and the *milk ring testing* in the dairy industry. In 2009, the National Surveillance Unit USDA-APHIS identified considerable redundancies in bovine brucellosis surveillance in regions classified as class free for bovine brucellosis for at least 5 years.19 Consequently, slaughter surveillance was reduced, and brucellosis milk surveillance was eliminated in 2011.

Market Cattle Testing

Surveillance by this method is part of the marketing process. Testing is done at livestock markets, slaughterhouses, livestock buying stations, or dealer premises. This type of testing is very effective, especially if required at the first point of assembly of cattle after leaving the farm of origin. Until 2011 95% or more of cows and bulls 2 years of age or older were required to be tested for brucellosis at slaughter in the United States. As of 2011 the number of slaughter plants participating in slaughter surveillance testing was reduced to 13 of the 40 top establishments and two bison slaughter plants. These slaughter plants are located in 13 states, representing all regions of the country.

Milk Ring Testing

Surveillance by this method involves the regular, periodic testing of milk or cream from commercial dairy herds. Milk ring testing is required twice annually in commercial dairy herds in states officially declared free of brucellosis, and four times annually in states not officially free of brucellosis. This test is very sensitive and is done on a small sample of milk from the entire herd. The milk ring test itself is simple and inexpensive. A well-managed testing program is important to public health and can reduce the exposure potential of contaminated dairy products to humans by quickly identifying affected herds. Routine brucellosis ring testing was discontinued in the United States in 2011, following the recommendation of the National Surveillance Unit of the USDA-APHIS that had identified redundancies in the diagnostic surveillance of bovine brucellosis in regions free of brucellosis for over 5 years.19

Australia

In Australia, under range conditions, considerable progress toward eradication of brucellosis in large beef herds has been possible. Management must be motivated and confident that the disease can be permanently eradicated. All cattle should be permanently identified, security between subherds must be good, vaccination histories must be accurate, and accurate round-up (mustering) of cattle must be possible. Quarantine facilities for infected subherds must be strict and absolutely reliable, and fence lines must be impenetrable. The development of a two-herd system, based on segregation of weaned heifer calves from adult cows and maintenance of testing pressure on the adults, will reduce the chance of infection of heifers. All calves from reactor dams are discarded, which necessitates positive identification. Only bulls or semen from brucellosis-free herds should be used in clean herds. In some situations, a laboratory is established on the ranch and equipped to do RBT and CFT. This increases the efficiency of the testing program and creates an excellent team effort between management, laboratory personnel, and the field veterinarian.

New Zealand

In New Zealand, the brucellosis status of accredited herds is monitored by a triennial CFT with a sensitivity of greater than 95%. Slaughterhouse surveillance, as performed in Australia, has a low probability of identifying infected herds. A skin test for brucellosis is attractive because it could be used at the same time as routine tuberculin testing.
Canada

In Canada, the bovine brucellosis eradication program is a success story that began in 1950 when the national prevalence of infection was about 9%. With the cooperative Federal–Provincial Calfhood Vaccination Program, the prevalence of infection was reduced to 4.5% by 1956. In 1957, a test and slaughter program was begun in which brucellosis control areas were established and mandatory testing of all cattle was done using the tube agglutination test. Reactors were identified and ordered to be slaughtered, and compensation was paid. Infected herds were quarantined and retested until negative or in some cases completely depopulated. When the infection rate was reduced to below 1% of the cattle population and 5% of the herds, the area was certified for a period of 3 years. When the infection rate was reduced to below 0.2% of the cattle in the area and 1% of the herds, the area was designated brucellosis free and certified for a period of 5 years. In the 1960s, the milk ring test and the market cattle testing programs were introduced as surveillance procedures. These are done on a continuing basis, are effective in locating infected herds, and have reduced the volume of on-farm testing required to recertify areas.

When the national level of infection was reduced to below 0.2%, calfhood vaccination was deemphasized to overcome the problem of distinguishing between persistent vaccination titers and titers caused by natural infection. Thus all seropositive animals could be disposed of and no vaccination privileges allowed. In 1973, an increase in the incidence of brucellosis occurred, which necessitated some modifications in the eradication program. The intensity of milk ring testing was increased, herds adjacent to infected herds were tested, the length of quarantine of infected herds was increased, and calves from reactor dams were ordered to be slaughtered. In heavily infected herds and in those in which it is not possible to maintain effective quarantine, it was preferable to completely depopulate a herd rather than conduct tests and successive retests. In the Canadian experience, brucellosis-free herds usually became infected when the owner unknowingly purchased an infected animal. The uncontrolled movement of infected animals from infected herds to brucellosis-free herds was a major obstacle in the final stages of the eradication program. The rate of progress in an eradication program is determined mainly by the rate at which herds that are accredited free of the infection become reinfected. The severity of reinfestation (or breakdown) is dependent on the proportion of the herd that has been vaccinated as calves. The cessation of compulsory calfhood vaccination results in a large proportion of cattle that are fully susceptible to B. abortus infection. The prevention of reinfestation requires a constant surveillance system. Canada was declared free of bovine brucellosis in 1985. In 1997, a comprehensive review of Canada’s bovine brucellosis surveillance program was undertaken. As a result of the findings of this review, a number of modifications to the surveillance program were introduced in 1999. The routine serologic testing of market and slaughter cattle and the routine milk ring testing of all dairy cattle were discontinued in 1999. However, auction market testing of cattle 24 months and older continues in the five markets in northern Alberta and British Columbia in response to the disease risk associated with the infected free-roaming bison herds in and around Wood Buffalo National Park.

In April 2000, the vaccination of calves with reduced dosage strain 19 B. abortus vaccine was discontinued. Strain RB51 B. abortus vaccine is not licensed for use in Canada.

Bovine brucellosis in wildlife is restricted to free-roaming bison in and around Wood Buffalo National Park in northern Canada. Information on this occurrence is found in Canada’s report to the OIE Wildlife Diseases Working Group.

Infectious Diseases Primarily Affecting the Reproductive System

Host Occurrence
In nature mainly sheep are affected, with the ram more susceptible than the ewe. A small number of natural cases occur in farmed red deer (Cervus elaphus) in New Zealand, but most infections resolve after 340 days and it is regarded as a self-limiting disease. It is difficult to establish infection in laboratory animals. However, white-tailed deer and goats can be infected experimentally and develop epididymitis. There is no evidence of natural infection in goats, even in those that graze with infected sheep.

The Merino breed and Merino-derived crossbreeds show a much lower incidence of the disease than do British breeds. The disease is most important in large flocks where there is multisire breeding.

Source of Infection
The infected ram is the source of infection and perpetuates the disease in a flock. The majority of infected rams excrete the organism in semen, and in most rams the active excretion in semen probably persists indefinitely. Ewes are more resistant to infection, but the organism can be isolated from them in infected flocks. After being bred by an infected ram, the majority will not carry infection for more than one or two heat cycles. Infection may result in early embryonic death and occasionally abortion or the birth of weak and poorly viable lambs. In ewes where the infection does persist to produce abortion, the organism is present in the placenta, vaginal discharges, and milk.

Transmission
Transmission between rams occurs via passive venereal infection and by direct ram-to-rum transfer. Passive venereal infection occurs from ewes that have been bred by an infected ram in the same heat cycle. Under natural conditions, this may be the major form of transmission from ram to ram during the breeding season. Infection can also be transmitted between rams in the non-breeding season when housed or grouped together on pasture. This occurs as they sniff and lick each other’s prepuce and by homosexual activity. Submissive rams may lick the prepuce of dominant rams as a trait in the dominance hierarchy. Spread of infection in a group of virgin rams is recorded. Lambs born from infected ewes and drinking infected milk do not become persistently infected.

The organism can survive on pasture for several months, but transmission by fomites appears to have no practical significance. However, transmission from infected rams to infection-free red deer stags grazed on the same pasture can occur, and it is not known if this results from direct contact between the animals or indirectly via environmental and pasture contamination.

Host Risk Factors
All postpubertal rams are susceptible to infection, but disease is more common in adult rams and disease prevalence increases with age, probably because of greater exposure to infection. Differences between flocks in the prevalence of disease suggest that environmental factors and stress may modulate susceptibility, but the risk factors are poorly defined. When the number of affected rams in a flock is greater than about 10%, the fertility of the flock is appreciably decreased.

Experimental Reproduction
Experimentally, rams can be infected by the IV, subcutaneous, intratesticular, oral, conjunctival, and preputial routes, but the latter two are the most effective. The first observable abnormality is the presence of inflammatory cells in the semen, which appear at 2 to 8 weeks. B. ovis appears in the ejaculate at approximately 3 weeks, but it is not always present in an infected ram after that. Testicular and epididymal lesions can be palpated at about 9 weeks after infection but may occur earlier in some rams. A significant proportion of infected rams have no palpable lesions but still excrete the organism.

Ewes in early pregnancy can also be infected by the oral and IV routes, but many of these infections are transient and do not result in abortion. Abortion caused by placentitis has been produced experimentally. Intrauterine infection produced experimentally also causes lesions in and death of the fetus, but the significance of this to natural cases is undetermined.

Economic Importance
The economic effects of the disease are subtle but significant. The effect of the disease on ram fertility can influence the number of rams that are required in a flock, with the required ram to ewe ratio significantly reduced in B. ovis–free flocks. The percentage of lambs born early and within the first 3 weeks of the lambing period is also markedly increased. Lambing percentage may be reduced by 30% in recently infected flocks and by 15% to 20% in those where the infection is endemic. The loss of rams of high genetic potential and the need for repeat serologic testing are additional costs. In the United States, the advantage in a control program has been calculated as an additional return of $12 per ewe mated.

Zoonotic Implications
B. ovis is not a zoonosis, but live Brucella vaccines used for prevention of this infection in some countries, such as Rev. 1 B. melitensis vaccine, are pathogenic to humans and should be handled and used with care.

PATHOGENESIS
There is an initial bacteremia, often with a mild systemic reaction, and the organism can be isolated from the internal organs of animals slaughtered after experimental infection. However, systemic disease is not a feature of the natural disease, and clinical disease results from localization and inflammation in the epididymides, typically in the tail. Inflammation in this area results in sperm stasis and extravasation with a subsequent immunologic reaction that is often unilateral, causing a spermatocele and reduced fertility. Not all infected rams have palpable lesions in the epididymis, and infection can also establish in the seminal vesicles and ampullae. In either case the organism is shed in the ejaculate.

Generally, B. ovis has low pathogenicity for ewes. The primary effect is a placentitis, which interferes with fetal nutrition, sometimes to the point of causing fetal death, but more commonly producing lambs of low birth weight and poor viability.

Analysis of the immune response by microarray hybridization and reverse transcription (RT)-PCR found that infection with B. ovis causes upregulation of genes involved in phagocytosis and downregulation of host defense mechanisms, both of which probably contribute to the chronic nature of the infection.

CLINICAL FINDINGS
The first reaction in rams is a marked deterioration in the quality of the semen together with the presence of leukocytes and Brucella. Acute edema and inflammation of the scrotum may follow. A systemic reaction, including fever, depression, and increased respiratory rate, accompanies the local reaction.

Regression of the acute syndrome is followed, after a long latent period, by the development of palpable lesions in the epididymis and tunicae of one or both testicles.

The palpation of both testicles simultaneously is the best method of examination. The epididymis is enlarged and hard, more commonly at the tail; the scrotal tunics are thickened and hardened; and the testicles are usually atrophic. The groove between the testis and epididymis may be obliterated.

The abnormalities are often detectable by palpation, but many affected rams show no acute inflammatory stage and others may be actively secreting Brucella and poor-quality semen in the chronic stage in the absence of palpable abnormalities. Palpable abnormality of the scrotal contents may be present in less than 50% of serologically positive rams. Affected rams have normal libido.

There are usually no clinical signs in the ewe but in some flocks infection causes abortion or the birth of weak or stillborn lambs, associated with a macroscopic placentalitis.
In red deer, only a small proportion of stags infected with *B. ovis* develop epididymitis detectable by scrotal palpation. In contrast to rams, in most stags the infection resolves within 12 months following infection.²

**CLINICAL PATHOLOGY**

Semen examination, including culture of the ejaculate, and serologic tests are used in suspect individuals and in groups of rams. The complement fixation and ELISA tests are by far the most useful; many infected rams have palpably normal scrotal contents and microbiologically negative semen. Ultrasound examination of the scrotal contents can reveal anechoic areas that correspond to foci of fibrosis, but these appear no earlier and are nonspecific, offering no real advantage over scrotal palpation.³

Multiplex PCRs to differentiate *B. ovis* from *Actinobacillus seminis* and *Histophilus ovis* have been described for use on semen or urine.⁶ Real-time PCR has also been used to type *Brucella* from field material, such as ovine placenta, without the need for culture.⁸

**Semen Examination**

A combination of semen examination and palpation of the testicles for abnormalities will identify approximately 80% of infected rams. In affected animals the findings are a general reduction in semen quality, a reduced total sperm output, poor motility, and a high proportion of spermatozoa with secondary morphologic abnormalities.

**Culture**

*B. ovis* is fastidious in its growth and requires special cultural techniques. The examination of the semen for the presence of leucocytes has been used to determine those sheep that should be cultured for *B. ovis*, but it is not a highly sensitive screening test. PCR for detection of *B. ovis* in semen has an equivalent sensitivity to culture.

**Serology**

The CFT, the standard test in many countries, is the prescribed test for international trade, and when used in conjunction with genital palpation has allowed the eradication of *B. ovis* from flocks. However, a small proportion of infected rams are negative to CFT, which can compromise or delay eradication programs. The sensitivity and specificity of the various serologic tests depend mainly on the antigens used and the serologic cut points, which may vary between countries and laboratories. A UK study reported the sensitivity of an ELISA, gel diffusion, and CFT as 97.6, 96.4, and 92.7%, respectively, with all tests 100% specific. Studies in other countries support this ranking, but others suggest that the ELISA has no advantage over the classic complement and gel diffusion tests. A combination of serologic tests may increase the sensitivity closer to 100%, but will obviously increase testing costs. Seroconversion occurs slightly earlier with the ELISA, compared with the complement fixation and gel diffusion tests, so it may be useful in situations where infection is rapidly spreading within a group of rams.⁸

Serologic tests will not differentiate vaccinated from infected sheep or sheep infected with *B. melitensis*.

**NECROPSY FINDINGS**

In the acute stage, there is inflammatory edema in the loose scrotal fascia, exudate in the tunica vaginalis, and formation of granulation tissue. In the chronic stage, the tunics of the testes become thickened and fibrous and develop adhesions. There are circumscribed indurations in the epididymis and these granulomata may also be present in the testicle. In advanced stages, they undergo caseation necrosis. As the epididymis enlarges the testicle becomes atrophied. *B. ovis* can usually be isolated from the genital organs, especially the tail of the epididymis, and rarely from internal organs and lymph nodes. Similar lesions are described in red deer stags.⁵

The abortus is characterized by thickening and edema, sometimes restricted to only a part of the placenta, with firm, elevated yellow-white plaques in the intercotyledonary areas and varying degrees of cotyledonary necrosis. Microscopically, organisms are visible within the cytoplasm of trophotrophoblasts of the inflamed placenta. A vasculitis is often present. The organism can be isolated from the placenta and the stomach and lungs of the lamb.

**Samples for Confirmation of Diagnosis**

- Bacteriology and PCR: epididymal granuloma, seminal vesicle, inguinal lymph node/fetal lung, stomach content, placenta (culture, has special growth requirements; cytology, Stamp’s or Koster’s stain on placental smear; PCR)
- Histology: formalin-fixed epididymis, testicle, seminal vesicle, inguinal lymph node from rams; in abortions placenta, fetal lung, liver, spleen, kidney, heart, brain

**DIFFERENTIAL DIAGNOSIS**

Infection with *Actinobacillus seminis* and *Histophilus ovis* can cause similar scrotal lesions, although many rams with abnormalities of intrascrotal tissues do not have brucellosis or infectious epididymitis. Abortion in ewes may be associated with a number of infectious diseases, which are summarized in Table 18-1.

**TREATMENT**

Treatment of naturally occurring cases is rarely undertaken. IM administration of long-acting oxytetracycline at 20 mg/kg body weight (BW), given every 3 days for 24 days, along with the daily IM administration of 20 mg/kg of dihydrostreptomycin sulfate, resulted in bacteriologic cure of 90% of experimentally infected rams. Oxytetracycline alone is less effective, but the use of dihydrostreptomycin is prohibited in food-producing animals in many countries. Treatment is economically feasible only in valuable rams and must be instituted before irreparable damage to the epididymis has occurred. The treatment of rams that are infected but without palpable lesions results in a significant improvement in breeding soundness classification on examinations subsequent to treatment.

**CONTROL**

Control is by preventing the spread of infection between rams and detecting and culling infected rams. In small flocks, culling of all rams and replacement with *B. ovis*–free rams may be the most cost-effective approach. Some control can be achieved using scrotal palpation to detect infected rams, but this must be combined with repeated serologic testing if eradication is the goal. Vaccination may be the most economical and practical means of controlling the disease in areas with a high incidence of infection and in regions of the world where eradication by test and slaughter is impractical.

**Eradication**

In a flock where the diagnosis has been confirmed all rams are palpated and those with scrotal abnormalities are culled. The remaining rams are tested serologically and reactors culled. Serologic tests are repeated at monthly intervals, with culling of reactors, until all rams are serologically negative. Further tests, 6 and 18 months later, are used to confirm eradication.

Infection spreads rapidly during the mating season, so eradication should be delayed until after the breeding season. During breeding it may be wise to run two breeding flocks, with virgin rams and rams known to be free of infection separated from older or suspicious rams (seropositive and/or those with scrotal lesions). Strict separation of the two ram flocks must be maintained at all times, and the clean group must not mate ewe flocks that have been mated to the suspect rams.

Several countries have voluntary accreditation schemes based on inspection of boundary fencing, restricting the introduction of new rams to those from accredited flocks and serologic testing.

**Vaccination**

A number of vaccines have been used, but none is fully effective. In some countries, vaccination is not permitted and eradication by test and slaughter is the only method of control.

CFT, complement fixation test; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.
Killed *B. ovis* vaccines, even with adjuvants, have poor efficacy. The use of a killed vaccine may be inadvisable in flocks where eradication is being attempted, because it may protect against clinical disease but allow a carrier state in some rams in which there is excretion of the organism in animals that become seronegative. An experimental vaccine prepared from enriched OMPs and rough LPS of *B. ovis* gave equivalent protection in challenge studies to that given by *B. melitensis* Rev. 1 vaccine.

A combined vaccine containing killed *B. ovis* in an adjuvant and *B. abortus* strain 19 also provided durable immunity but had several disadvantages. Vaccinated animals become seropositive, which compromises the subsequent use of serologic tests for eradication. Strain 19 also can cause epididymitis, and vaccinated rams may excrete strain 19 in their semen.

Live *B. melitensis* strain Rev. 1 has been found to be most effective and is the most widely used vaccine, where permitted. This strain was developed in the 1950s from a virulent isolate that had become streptomycin dependent. It is avirulent for rams, and subcutaneous or conjunctival vaccination provides protection against experimental and field challenge. Vaccinated animals become positive to the complement fixation test and ELISA tests, but titers are low and can be minimized by using the conjunctival route for vaccination. However, vaccinated animals can excrete *B. melitensis* strain Rev. 1, and it can cause abortions, so alternative vaccine candidates are being evaluated. These include an OMP extracted from *B. melitensis* (Omp31) and an attenuated strain of *B. ovis* (Delta abcBA). The latter protects against experimental challenge with virulent *B. ovis* and is considered a potential vaccine strain for rams.

If vaccination is used there should also be a program of culling clinically abnormal rams, and ram replacements should be yearlings vaccinated at 4 to 5 months.

### REFERENCES

### ETIOLOGY

It is a small, aerobic, gram-negative *Bacillus*. Remember that *B. abortus* and *B. melitensis* will also occasionally infect the pig, however, only *B. suis* will cause systemic and generalized infections in pigs. The other species will infect pigs, but the infection is self-limiting and the infection is usually restricted to the local lymph nodes. There are five biovars.

### EPIDEMIOLOGY

#### Geographic Occurrence

**Biovar 1**

Biovar 1 is important in pigs and occurs worldwide, but the disease has not been recorded in the UK, Canada is disease free, and the prevalence is very low in the United States. It is particularly important in the Philippines and the Pacific islands and Africa.

**Biovar 2**

Biovar 2 occurs in pigs in west central Europe, particularly Croatia and Czechoslovakia, and also in hares. There appears to be a close relationship between pigs and wildlife in this strain and wild boar in particular. Occasionally it appears in cattle, dogs, and horses.

**Biovar 3**

Biovar 3 has a close similarity to *B. melitensis* biovar 2 and requires phage typing, oxidative metabolic testing, or PCR for differentiation. It also occurs in pigs in the United States, South America, and southeast Asia. It is a problem in wild boar where it may reach 8% to 32% prevalence, and particularly in Italy and Spain, the spill over from wild boar to domestic pigs is a particular problem.

**Biovar 4**

Biovar 4 is a cause of rangiferine brucellosis (reindeers, caribou, bison, moose, etc.) and can transmit to cattle but does not appear to be a disease of pigs. It will transmit to humans.

**Biovar 5**

Biovar 5 is murine brucellosis. It may also include *B. microti*, which has been isolated from voles and wild rodents in Russia.

### Host Occurrence

Domestic, wild, or feral pigs are the host for biovar types 1 and 3, and widespread infection in feral pigs is recorded in Queensland, Australia, and the southern states of the United States. Bison may remain reservoirs. Incursion to domestic pigs from wild boar is an increasing problem. Cattle and horses may be infected, especially if they share a range with feral pigs, and this association adversely affects the status of cattle herds undergoing brucellosis eradication programs. Cattle are noncontagous hosts, but an outbreak in Switzerland where the disease had not appeared since 1946 has been attributed to a spread of infection from horses.

**Biovar 1**

Biovar 1 has been isolated from the semen of a ram. Infection in dogs, usually symptomless but occasionally producing orchitis or epididymitis, or granulomas can result from eating raw pig meat.

**Biovar 2**

In addition to the pig, the European hare (*Lepus capensis*) is also a major host for biovar 2, and this biovar is common in central Europe. Some studies have suggested that the type found in hares in Europe is a different strain from the wild boar.
Biovar 4
Biovar 4 can transmit to cattle in contact with infected reindeer. Wild canids can also be naturally infected with biovar 4, presumably by ingestion.

Source of Infection
Infected boars can shed $10^3$ to $10^7$ colony-forming units (CFU) of *B. suis* per milliliter of semen. The bacterium is also shed in the milk.

The introduction of infected pigs, usually a boar or the communal use of an infected boar, is the common means of introduction of the bacterium into a pig unit. Artificial insemination using noncertified or untreated semen can also spread the disease as can ova. Transmission usually requires direct or close contact and is usually oral. Discharges in milk and uterine secretions are infectious. Sows may be carriers and piglets can spread the disease horizontally. It is thought that infection through the conjunctiva is also a possibility. It probably does not survive in the environment unless contained in organic matter under cold conditions. Within a piggery the disease is spread by ingestion and by coitus. The ingestion of food contaminated by infected semen and urine and discharges from infected sows are also important methods of spread. Dried secretions, if frozen, may remain infective. Most disinfectants and sunshine kill the virus.

The feeding of kitchen waste containing raw pig meat also presents a risk. Domestic herds are also at risk when they are kept under extensive husbandry methods in areas where there is a high prevalence of infection in feral pigs. Cattle infected with biovar 1 are noncontagious to other livestock and can have normal pregnancies and give birth to uninfected calves.

Wild animals, including hares and rats, may provide a source of infection with biovar 2, and ticks are also suspected of transmitting the disease.

Host and Pathogen Risk Factors
The fact that *B. suis* survives so well in raw meat, e.g., 128 days in sausage meat, means that prepared pork products are always a source of infection. They can survive freezing for over 2 years. Environments and pastures can be infected for a long period of time.

*B. suis* is more resistant to adverse environmental conditions than *B. abortus*, although its longevity outside the body has not been fully examined. It is known to survive in feces, urine, and water for 4 to 6 weeks. As the environmental temperature rises, the survival in the environment decreases. It is also deactivated by bright sunlight. It has also been known to survive desiccation.

Among pigs, susceptibility may vary with age. The prevalence of infection is much higher in adults than in young pigs, although this may represent an exposure risk rather than an age-related risk. Susceptibility is much greater in the postweaning periods and is the same for both sexes, but there may also be genetically determined differences in susceptibility. Some piglets acquire infection from the sow, either from the ingestion of infected milk or by congenital infection.

Lateral spread through a herd is rapid because of the conditions under which pigs are kept. No durable herd immunity develops and, although a stage of herd resistance is apparent after an acute outbreak, the herd is again susceptible within a short time and the bacteria can spread rapidly on entry to a herd. Within a few months 50% may be infected and 70% to 80% may be involved at the start of the outbreak. Further outbreaks may occur if infection is reintroduced.

In an enzootic area, the proportion of herds infected is usually high (30%–60%). The prevalence of seropositivity in an infected herd varies but can be as high as 66%. Seroprevalence in feral pigs is also high, but rarely have lesions and genital infections that may be a major source of infection. Protective clothing, such as gloves, protective clothing, eye protection, and protection of any bare skin, is essential.

Economic Importance
The disease is economically important because of infertility and reduction in numbers of pigs weaned per litter. Mortality in live-born piglets, which occurs during the first month of life, may be as high as 80%. The mortality rate is negligible in mature animals, but sows and boars may have to be culled because of sterility, and occasionally pigs are culled because of posterior paralysis.

In addition, eradication involves a great deal of financial loss if complete disposal of a registered herd is undertaken.

Zoonotic Implications
Biovar 2 is not a zoonosis, but biovars 1, 3 (as pathogenic as *B. melitensis*), and 4 have considerable significance for public health and are very pathogenic to humans. In countries where pigs are a significant part of animal production, human brucellosis is another major economic cause of injury to the swine producer.

In infected cattle, *B. suis* localizes in the mammary gland without causing clinical abnormality and, where cattle and pigs are run together, the hazard to humans drinking unpasteurized milk may be significant. Biovar 4 causes human disease associated with consumption of contaminated meat. Human brucellosis at a pig slaughterhouse in Argentina has been described. The median age of the slaughterhouse workers was 40 (23–65) and they had worked for 1 to 9 years in the slaughtering or butchery part of the plant. A systemic or localized disease with recurrent episodes was described. The chronic disease may be progressive. The patients’ serum antibody titers (SAT) titers ranged from 1:25 to 1:12,800 and CFT from 1:10 to 1:1280. Of the pigs tested, 11% of the males (7/62) and 18% of the females (25/138) were positive.

In infected cattle, *B. suis* is more resistant to adverse environmental conditions than *B. abortus*, although its longevity outside the body has not been fully examined. It is known to survive in feces, urine, and water for 4 to 6 weeks. As the environmental temperature rises, the survival in the environment decreases. It is also deactivated by bright sunlight. It has also been known to survive desiccation.

Among pigs, susceptibility may vary with age. The prevalence of infection is much higher in adults than in young pigs, although this may represent an exposure risk rather than an age-related risk. Susceptibility is much greater in the postweaning periods and is the same for both sexes, but there may also be genetically determined differences in susceptibility. Some piglets acquire infection from the sow, either from the ingestion of infected milk or by congenital infection.

Lateral spread through a herd is rapid because of the conditions under which pigs are kept. No durable herd immunity develops and, although a stage of herd resistance is apparent after an acute outbreak, the herd is again susceptible within a short time and the bacteria can spread rapidly on entry to a herd. Within a few months 50% may be infected and 70% to 80% may be involved at the start of the outbreak. Further outbreaks may occur if infection is reintroduced.

In an enzootic area, the proportion of herds infected is usually high (30%–60%). The prevalence of seropositivity in an infected herd varies but can be as high as 66%. Seroprevalence in feral pigs is also high, but rarely have lesions and genital infections that may be a major source of infection. Protective clothing, such as gloves, protective clothing, eye protection, and protection of any bare skin, is essential.

PATHOGENESIS
Infection is followed by multiplication in the local lymph nodes. Only 10$^{12}$ organisms will produce an experimental infection, but the severity of the infection is not correlated with either the dose or the route of infection. As for the other species, *B. suis* requires the *virB* operon-encoded T455 for intracellular invasion and multiplication within host cells. The T455 mutants are not able to survive and multiply in macrophages or epithelial cells. As in brucellosis associated with *B. abortus*, there is initial systemic invasion possibly through the M cells of the lymphoid tissue in the gut, but also possibly the oral, nasopharyngeal, conjunctival, or vaginal mucosa. There is generally a long period of incubation before clinical signs appear. In young animals these are not necessarily visible and will depend mainly on the age, sex, and physiologic state of the animals at the time they are infected. The organism then appears in the bloodstream, usually within 1 to 7 weeks, and often lasts for 5 weeks but can persist for up to 34 weeks. However, infection with *B. suis* differs from that associated with *B. abortus* in that localized or localized infection occurs in several organs in addition to the uterus and udder, and the organism is found in all body tissues and produces a disease similar to endometritis in humans.

The organisms persist in lymph nodes, joints, bone marrow, and the genital tract. The more common manifestations of localization are abortion and infertility caused by localization in the uterus; lymphadenitis, especially of the cervical lymph nodes; arthritis and lameness caused by bone and joint localization; and posterior paralysis caused by osteomyelitis. In boars, involvement of the testicles
often leads to clinical orchitis, and the boars are probably infected for life. Widespread infection makes handling of the freshly killed carcasses hazardous and creates a risk for brucellosis in humans eating improperly cooked pork.

**CLINICAL FINDINGS**

Do not forget that clinical signs in pigs may also be produced by *B. abortus* and *B. melitensis*. Porcine brucellosis is usually a more generalized and chronic disease than bovine brucellosis. The clinical findings in swine brucellosis vary widely, depending on the site of localization. The signs are not diagnostic, and in many herds a high incidence of reactors is observed with little clinical evidence of disease. Reproductive inefficiency is the common manifestation.

**Sows**

Infection at service usually results in early abortion, sometimes as early as 17 days after natural service with infected boars, with return to estrus at 5 to 8 weeks after service, which may be the only sign that infection has taken place.

Infertility, irregular estrus, small litters, and abortion occur. Later infection will give rise to mummification and stillbirths. The incidence of abortion varies widely between herds but is usually low and is usually early. Infection of the fetus may lead to abortion. As a rule, sows abort only once in a lifetime, and this is most common during the third month of pregnancy. Affected sows usually breed normally thereafter. Sows may remain carriers and may shed organisms in milk and uterine discharges, which may be extremely bloody and may be accompanied by endometritis and retained fetal membranes.

**Boars**

Orchitis with testicular swelling, epididymitis, and necrosis of one or both testicles is followed by sterility usually within 7 weeks of infection. Lameness, incoordination, and posterior paralysis are fairly common. The onset is gradual, and signs may be caused by arthritis or, more commonly, osteomyelitis of lumbar and sacral vertebral bodies. Testicular atrophy may result at around 19 weeks. Boars have a low rate of recovery (less than 50%). After infection, enough animals remain infected to perpetuate the disease. In both sows and boars, the bones and joints may be involved, and in these cases there may be posterior paralysis and lameness. Nodules may be seen in the spleen and liver and abscesses may be seen in boars.

**Piglets**

A heavy mortality in piglets during the first month of life is sometimes encountered, but most piglet loss results from stillbirths and the death of weak piglets within a few hours of birth. Up to 10% may contract infection when they are young and retain the infection until adulthood.

**CLINICAL PATHOLOGY**

**Culture**

Laboratory identification of the disease is difficult. It should be routine to use more than one culture method. Isolation of the organism should be attempted if suitable material is available. Such material for culture includes aborted fetuses, testicular lesions, abscesses, blood and lymph nodes (particularly the submandibular, gastrointestinal, and external iliac nodes). The organism is a small, slender, aerobic gram-negative organism that produces 1- to 2-mm colonies on blood agar after 2 to 4 days. A new method of culture has been described for *B. suis* called LNV-M. Interestingly, in a study of wild boar the organism was isolated from 93% of males but only 61% of females. PRCs using the omp 2b gene or RT-PCR may be more reliable. *B. suis* can be differentiated from the other species by PCR, although it may be less successful than culture.

A fingerprinting technique based on a PCR method for multilocus variable number tandem repeat analysis (MLVA) has been developed.

There is no PCR test for differentiating the five biovars from each other.

**Serology**

Antibodies are usually developed 6 to 8 weeks after infection. These tests are only useful on a herd basis. There is no satisfactory serologic test. Some animals remain seronegative to all tests. Recently indirect or competitive ELISAs have been developed and may be 98% and 100% specific.

An ELISA compared with complement fixation was found to be just as sensitive and as specific a test for both pigs and hares for *B. suis* infections. A meat juice ELISA has also been shown to be a valuable method for testing both hares and wild boars. There is considerable individual variation in the antibody response of pigs following infection, and some may be culture positive but have negative or indefinite titers to the common tests. Pigs under 3 months of age have a poor antibody response to infection.

Serologic tests in common use include the rose Bengal plate agglutination test, Rivanol test, rose Bengal card test, complement fixation, agar gel immunodiffusion, and tube agglutination. The preferred test varies between countries but most use the rose Bengal plate or card test. *B. abortus* antigens are used for diagnosis because *B. suis* has the same surface LPS antigens. Estimates of the sensitivities of the complement fixation and tube agglutination tests range from 40% to 51%, and they range from 62% to 79% for the rose Bengal plate test. The immunodiffusion test has poorer sensitivity than the standard serologic tests. The sensitivity and specificity of all the tests have been shown to vary with the stage of infection in the experimental disease, and it has been recommended that more than one test should be used for diagnosis. A recent study showed a range of sensitivity from 84% to 100% with the CFT low at 84% and the serum agglutination test high at 100%. The sensitivities ranged from 79.7% to 100%, with the serum agglutination test low at 79.7% and iELISA and C-ELISA high at 100%. A recent validation of the polarization assay as a serologic test for the presumptive diagnosis of porcine brucellosis has shown promise. Tests have been reviewed, and both authors say that the problem is cross-react with *Yersinia O9*.

**NECROPSY FINDINGS**

On necropsy, there may be arthritis, posterior paralysis, spondylitis, and abscess formation in both sexes. The lesions are usually granulomatous as a result of persistent cytokine release, and these may be in the liver, kidney, spleen, and reproductive tracts.

Many organs may be involved in chronic cases. Chronic metritis manifested by nodular, white, inflammatory thickening, 2 to 5 mm in diameter, and abscessation of the uterine wall is characteristic with or without hemorrhage and necrosis. Arthritis may be purulent, and necrosis of vertebral bodies in the lumbar region may be found in lame and paralyzed pigs. The clinical orchitis of boars is revealed as testicular enlargement or atrophy and testicular necrosis, often accompanied by lesions in the epididymis and seminal vesicles. Splenic enlargement and pronounced lymphadenopathy, caused by hyperplasia of mononuclear phagocytes, occur in some cases. Typical histologic changes consist of granulomatous inflammation with neutrophils, macrophages, and giant cells and hyperplasia of reticular tissues and foci of caseous necrosis in the liver, kidney, spleen, and reproductive tract.

**DIAGNOSIS**

Diagnosis is suggested by the clinical signs, the necropsy findings, clinical pathology, and epidemiologically by the presence of wild boar locally. None of the tests is capable of diagnosing disease in the individual animal. The real problem of diagnosis is the cross-reactions with *Y. enterocolitica* O:9 infection. In a survey of slaughter pigs in the UK 10% were found to have *Y. enterocolitica* in their gut. There are false positives caused by this organism in initial screenings as the antibody lasts 2 to 9 weeks following *Y. enterocolitica* infection. They can be eliminated by testing for cellular immunity by measuring the IFN-γ generation by leukocytes.

Internationally accepted tests for swine brucellosis include ELISAs, FPA, RBT, buffered plate agglutination test, and the CFT.
Samples for Confirmation of Diagnosis

- Bacteriology: adults, culture swab from joint, lymph nodes, spleen, uterus, epididymis, or other site of localization; fetus, lung, stomach content, placenta (has special growth requirements)
- Histology: formalin-fixed samples of above tissues (light microscopy)

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

DIFFERENTIAL DIAGNOSIS

The protean character of this disease makes it difficult to differentiate. Syndromes that need differentiation include:
- Abortion and infertility in sows
- Posterior parasis diseases of spinal cord
- Mortality in young pigs is also caused by many agents, and the important entities are listed in Chapter 19 in the section on Perinatal Disease—General Epidemiology.

TREATMENT

Treatment with a combination of streptomycin parenterally and sulfadiazine orally, or with tetracycline, is ineffective, although combinations of oxytetracycline, streptomycin, and possibly gentamicin have been used.31 It is unlikely that treatment will ever be attempted on a commercial scale.

CONTROL

Vaccination

No suitable vaccine is available.31 Strain 19 B. abortus, B. abortus "M" vaccine, living attenuated B. suis vaccines, and phenol and other extracts of B. suis are all ineffective. In a recent study, a natural rough mutant of B. suis that does not induce adverse clinical effects or tissue localization but does induce significant humoral and cellular immune responses after vaccination in swine has been observed.32 The antibody responses to infection in any case are often not powerful enough to eliminate infection.

Test and Disposal

In herds where the incidence of reactors is high, complete disposal of all stock as they reach marketing age is by far the best procedure because of the difficulty in detecting individual infected animals. This is most practicable in commercial pork-producing herds. Restocking the farm should be delayed for 6 months after thorough disinfection is complete. The existing serologic tests can be used for certifying herds free of infection that can then provide replacement stock. Repopulation programs can also use specific pathogen-free pigs.

The alternative is to commence a two-herd segregation program, and this is recommended for purebred herds that supply pigs for breeding purposes. Total disposal is not usually economical in these herds. Once a herd diagnosis has been established, all the breeding animals must be considered to be infected; all piglets at weaning are submitted to the serum agglutination test, Rvanol, or other test and, if negative, go into new quarters to start the nucleus of a free herd. It is probably safer to wean the pigs as young as possible and test again before mating. If complete protection is desired, these gilts should be allowed to farrow only in isolation, should then be retested, and their piglets used to start the clean herd. A modified scheme based on the previously mentioned method of weaning and isolating the young pigs as soon as possible but without submitting them to the serum agglutination test has been proposed, but its weakness is that infections may occur and persist in young pigs.

After eradication is completed, breakdowns are most likely to occur when infected animals are introduced. All introductions should be from accredited free herds, should be clinically healthy, and be negative to the serum agglutination test twice at intervals of 3 weeks before introduction.

Eradication of swine brucellosis from an area can only be achieved by developing a nucleus of accredited free herds and using these as a source of replacements for herds that eradicate by total disposal. Sale of pigs and pigveying purposes from infected herds must be prevented.

With the advent of infection in wild boar and feral pigs, it is essential to maintain an effective separation from them when there are domestic pigs, and this is especially true where there are outdoor pig units. Recently contaminated wood has been shown to be a problem.33

REFERENCES

BRUCELLOSIS ASSOCIATED WITH BRUCELLA MELITENSI S

SYNOPSIS

Etiology Brucella melitensis.

Epidemiology Disease of goats, sheep, and occasionally cattle. Transmission congenital or by ingestion or contact with infected placenta, vaginal discharge, or milk.

Clinical findings Abortion storms, abortions often in last 2 months of pregnancy. Weak-born lambs. Important zoonotic disease in humans.

Clinical pathology Polymerase chain reaction (PCR) and culture of organism. Serologic tests and skin hypersensitivity testing for herd diagnosis.

Necropsy findings Placentitis.

Diagnostic confirmation Isolation of the organism, PCR.

Control Slaughter eradication. Vaccination with B. melitensis Rev. 1 vaccine, but this can cause abortion in pregnant animals.

ETIOLOGY

B. melitensis causes brucellosis in goats and sheep, is capable of infecting most domestic animal species, and is the primary cause of brucellosis of humans (Malta fever) in many countries. There are three biovars of the organism that have differing geographic distribution, but no difference in pathogenicity or animal species affected. There is a close relationship to other members of the genus, which currently has 10 species but is expanding with the advent of molecular typing.

EPIDEMIOLOGY

Geographic Occurrence

The distribution of Brucella melitensis is more restricted than that of B. abortus and its primary area of occurrence is in the Mediterranean region, including southern Europe. Infection is also present in west and central Asia, Mexico, countries in Central and South America, and in Africa. Northern Europe is free of infection, except for periodic incursions from the south, as are Canada, the United States, southeast Asia, Australia, and New Zealand.

The prevalence of brucellosis varies between countries and regions, but in many
countries the prevalence has declined in the past 20 years in association with mandatory vaccination policies. However, in many others it is not effectively controlled because of the low incomes or nomadic nature of those who farm small ruminants. Hence it is regarded as a neglected but very important disease of livestock and humans in developing countries.

Host Occurrence
Goats and sheep are highly susceptible. Susceptibility in sheep varies with the breed, with Maltese sheep showing considerable resistance. The organism is capable of causing disease in cattle and has been isolated from buffalo, yaks, camels, and pigs.

Source of Infection
The source of infection is the infected carrier animal. Transmission to a naive herd or flock occurs with the introduction of an infected animal, and persistence results from sheep or goats that are prolonged excretors. Excretion is from the reproductive tract and in milk.

Reproductive Tract
Infected does and ewes, whether they abort or give birth normally, discharge many brucelles in their uterine exudates and placenta. The organism can be present in uterine discharge for at least 2 months following parturition in infected goats. The vaginal exudate of infected virgin or open animals may also contain the bacteria, but transmission between animals is most likely from the massive exposure provided by an infected placenta.

Milk
The majority of goats infected during pregnancy will excrete the organism in milk in the subsequent lactation and many will excrete it in all future lactations. In sheep, the period of excretion of the organism from the uterus and in milk is usually less than in goats, but the organism can be present in milk throughout lactation. The duration of excretion in cattle is not known.

Transmission
Routes of infection for both adults and young are via ingestion, by nasal or conjunctival infection, and through skin abrasions, with infected placenta and uterine discharge as a major source.

In Utero Infection
Infection of the fetus during pregnancy does not necessarily result in abortion: infected kids and lambs may be born alive but weak, or they may be quite viable. In some cases the infection persists in a latent form until sexual maturity, when pregnant animals may abort the first pregnancy. However, others, if weaned early from their dams and from the infected environment, become free from the infection as adults.

Colostrum and Milk
Latent infection can also be acquired from the ingestion of infected colostrum and milk. This is a major route of transmission and perpetuation of infection in a herd or flock.

Host and Pathogen Risk Factors
The organism is reasonably resistant to environmental influences and under suitable conditions can survive for over 1 year in the environment. B. melitensis is susceptible to disinfectants in common use at recommended concentrations.

In goats and sheep, the infection of a naive herd or flock will produce an abortion storm, following which most animals are infected but immune, and further abortions are usually limited to young or introduced animals. Because of the limited periods of excretion in sheep the disease tends to be self-limiting in small flocks that have few new introductions. It can be a continuing problem in large flocks because of massive environmental contamination of areas used for pregnant and lambing ewes. In some areas the prevalence of brucellosis associated with B. melitensis is linked to the practice of animal movement to summer and mountain pastures in which there is commingling of sheep and goats from a variety of sources on the same pasture.

Spread in beef cattle is slow, presumably because they are usually farmed at lower stocking rates, whereas spread in dairy herds can be more rapid and extensive.

Economic Importance
Brucellosis has major veterinary and human importance in affected countries. Costs include production loss associated with infection in animals, the considerable cost of preventive programs, and human disease. There is further loss from restriction in international trade in animals and their products.

The occurrence of B. melitensis in the sheep and goat population of countries that have eradicated B. abortus poses a threat for the continuing occurrence of brucellosis in cattle herds.

Zoonotic Implications
B. melitensis is the most invasive and pathogenic for humans of the three classical species of the genus, and is the cause of Malta or Mediterranean fever in humans, which is an extremely debilitating disease. It is an important zoonosis in areas of the world in which B. melitensis is endoctic in goats and sheep. The disease in humans is severe and long-lasting and often occurs in communities with limited access to antimicrobial therapy. Control and eradication of the infection in animal populations has high priority in all countries.

Large numbers of organisms are excreted at and following parturition, providing a source of infection for humans managing the herd or flock and also for people in the immediate vicinity from aerosol infection with contaminated dust. The risk of infection is high in cultures that cohabit with their animals or when weak, infected newborn animals are brought into the house for warmth and intensive care. Milking of sheep and goats is usually manual, often with poor sanitation and milking-time hygiene. Raw milk and cheese products from infected goats, sheep, or cattle also provide a risk and were the mechanism for the occurrence of Malta fever that initiated the definition of the disease.

Abattoir workers, shearsers, and people preparing goat and sheep skins are also at risk. The risk for veterinarians is primarily from assisting birthing in infected animals and herds, but is also the examination of any animal that is subclinically infected. There is also the risk of accidental self-inoculation with live vaccine.

Vaccination of small ruminants with B. melitensis Rev. 1 vaccine is a primary method in controlling the human disease. In Greece, a 15-year period of vaccination was associated with a drop in the incidence of human brucellosis, but when this program was stopped the prevalence of abortions in animals and the incidence if brucellosis in humans increased dramatically, only to be controlled by the reinstitution of vaccination of animals as an emergency mass vaccination program. However, although the Rev. 1 vaccine is attenuated compared with field strains, it retains some virulence and incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact herds.

Because of its pathogenicity to humans and animals, B. melitensis is listed as an agent of bioterrorism and agroterrorism. It is thought that fewer than 10 CFU are capable of infecting humans via aerosols. This would require mass therapy of human populations and destruction of animal populations.

PATHOGENESIS
The organism is a facultative intracellular parasite. As in other forms of brucellosis, the pathogenesis depends on localization in lymph nodes, udder, and uterus after an initial bacteremia. In goats, this bacteremia may be sufficiently severe to produce a systemic reaction, and blood culture may remain positive for a month. Localization in the placenta leads to the development of placentitis, with subsequent abortion. After abortion, uterine infection persists for up to 5 months, and the mammary gland and associated lymph nodes may remain infected for years. Spontaneous recovery may occur, particularly in goats that become infected when they are not pregnant. In sheep, the development of the disease is very similar to that in goats. In cattle, B. melitensis has a similar pathogenesis and produces a persistent
infection in the mammary gland and the supramammary lymph node, with obvious significance for public health.

**CLINICAL FINDINGS**

Abortion during late pregnancy is the most obvious sign in goats and sheep, but as in other species there may be a storm of abortions when the disease is introduced, followed by a period of flock resistance during which abortions do not occur. Abortion is most common in the last 2 months of pregnancy. The excretion of the organism in milk is not accompanied by obvious signs of mastitis. Infection in males may be followed by orchitis, which is frequently unilateral.

In experimental infections, a systemic reaction occurs with fever, depression, loss of weight, and sometimes diarrhea. These signs may also occur in acute, natural outbreaks in goats and may be accompanied by mastitis, lameness, and bygrroma; however, they are uncommon in the natural disease and their occurrence in the experimental disease reflects a massive challenge dose. Osteoarthrosis, synovitis, and nervous signs may occur in sheep.

In pigs, the disease is indistinguishable clinically from brucellosis associated with *B. suis*.

In many instances, *B. melitensis* infection reaches a high incidence in a group of animals without signs of obvious illness, and its presence may be first indicated by the occurrence of disease in humans infected from the herd or flock. This is so in cattle where the infection is subclinical and does not produce abortion, but the organism is shed in milk.

**CLINICAL PATHOLOGY**

**Culture and Molecular Tests**

Positive blood culture soon after the infection occurs and isolation of the organism from the aborted fetus, vaginal mucus, or milk are the common laboratory procedures used in diagnosis. The organism is moderately acid fast, and staining smears from the placenta and fetus with a modified Ziehl-Neelsen method may give a tentative diagnosis; however, this does not distinguish this infection from *B. ovis* or the agent of enzootic abortion (*Chlamydia abortus*), and culture is required.

The organism can be detected by PCR in the abomasal fluid of aborted fetauses and, compared with culture, PCR has a sensitivity and specificity of 97.4% and 100%, respectively. PCR can also be used to detect the organism in tissues, semen, and milk. A real time RT-PCR has been used to type Brucella from field samples, such as ovine placenta, without the need for culture.

Multilocus variable-number tandem repeats analysis (MLVA) is an alternative to classical biotyping and may be useful in analyzing the epidemiology and source of outbreaks. For example, in 2011 a strain of *B. melitensis* in a single infected flock in Sardinia, a region of Italy free from this disease since 1998, was confirmed as being a rare American lineage and probably originating from Spain. Multiplex PCR and high-resolution melt point analysis has also been used to differentiate *Brucella* spp.

**Serology**

The conventional serologic tests for the diagnosis of *B. melitensis*—agglutination, CFT, and the rose Bengal or card test—use the same antigens that are used for the diagnosis of *B. abortus* infections (either whole cells or sLPS).

The RBT and CFT are the most widely used. These, plus iELISA and FPA are prescribed tests for international trade. The RBT is not 100% specific, but is typically used as a screening test with the CFT applied in series or parallel. RBT or CFT is not sufficiently sensitive to accurately detect infection in an individual animal. Nevertheless, they can be used to detect infected herds for slaughter eradication of the disease. They can be used for test and slaughter programs within an infected herd, but their reduced sensitivity makes this strategy less effective in sheep and goats compared with cattle. A combination of these tests and tests performed on several occasions may increase the accuracy of detection of infected animals. If only one test is possible, the CFT is recommended, but it suffers from the requirement for a sophisticated laboratory, which is not always available in affected areas.

Conventional serologic tests will not differentiate infection with different species of *Brucella* and will not differentiate infection associated with *Y. enterocolitica* type O:9.

Several ELISA tests have been evaluated for use in small ruminants, some using recombinant antigens such as Omp31 and others using whole-cell antigens. These include indirect, competitive, and blocking ELISAs. A C-ELISA had a diagnostic sensitivity ranging from 74% to 89%, depending on cutoff values, and a specificity from 93% to 97%. Comparisons of the FPA and commercial ELISA tests with the RBT and CFT have shown no great advantages over the older tests, with the iELISA often having a slightly greater sensitivity. Overall testing sensitivity may be improved if these tests are used in parallel.

**Allergic Tests**

An intradermal allergic test using 50 mg of brucellin INRA (purified and free from LPS) can be used for diagnosis. The injection sites in goats are the neck or caudal fold and in sheep the lower eyelid, with reactions read in 48 hours. The test has high specificity in flocks that are free of infection and not vaccinated. However, it has little advantage over conventional serologic tests in infected herds, and Rev.-1—vaccinated animals can react for at least 2 years. It has particular value in identifying some animals that are false-positive reactors, differentiating infections with *Y. enterocolitica* but not *B. ovis*. Anergy occurs between 6 and 24 days after injection.

**Necropsy Findings**

There are no lesions that are characteristic of this form of brucellosis. The causative organism can often be isolated from all tissues but the spleen, lymph nodes, and udder are the most common sites for attempted isolation in chronic infection.

**Samples for Confirmation of Diagnosis**

- **Bacteriology**: adults, spleen, lymph node, udder, testicle, epididymis; *fetus*, lung, spleen, placenta (culture: has special growth requirements; cytology: Stamps’ or Koster’s stain on placental smear; PCR; *fetus*, PCR of fetal abomasal fluid.
- **Histology**: formalin-fixed samples of the previously listed tissues.

The zoonotic potential of this organism means care needs to be taken when handling potentially infected material, and specimens should be properly packaged when submitted to a laboratory.

**Differential Diagnosis**

The primary differential is from other forms of brucellosis (seen in this chapter) and other causes of abortion in small ruminants.

**Treatment**

Treatment is unlikely to be undertaken in most animals because it is unlikely to be economically feasible or therapeutically effective. For example, a dose of 1000 mg per animal of long-acting tetracycline given every 3 days for 6 weeks achieved a cure rate of 75%.

**Control**

Hygiene

Control measures must include hygiene at kidding or lambing and the disposal of infected or reactor animals. Separate pens for kidding does that can be cleaned and
disinfected, early weaning of kids from their does and their environment, and vaccination are recommended. In endemic areas, all placentas and dead fetuses should be routinely buried.

**Eradication**

Where a group is infected for the first time it may be most economical to dispose of the entire herd or flock, because eradication by test and slaughter is prolonged by the lack of sensitivity of the serologic tests.

Many countries that have this disease have statutory control measures and the disease can be eradicated, such as from Cyprus. *B. melitensis* also can be eradicated, with difficulty, from dairy cattle. However, vaccination may be the only practical method of control in areas in which there is a high prevalence of the disease, extensive management systems, communal and nomadic grazing, and a low socioeconomic level.

**Rev. 1 Vaccination**

Rev. 1 vaccine is a live, attenuated *B. melitensis* strain derived from a virulent *B. melitensis* isolate that is resistant to dihydrostreptomycin. It is the reference vaccine strain that provides protection against infection with *B. melitensis* in sheep and goats and against infection with *B. ovis* in rams. However, this vaccine has significant disadvantages, including persistent serologic response and, although attenuated compared with field strains, it retains some virulence. Incorrect selection from the seed stock can result in vaccines with considerable virulence for both vaccinated animals and in-contact humans.

Vaccination with Rev. 1 produces a bacteremia that is cleared by 14 weeks in goats and a shorter time in sheep. Vaccination at 3 to 8 months of age confers a high degree of immunity that lasts for more than 4 years in goats and 2½ years in sheep. The initial recommendations were to vaccinate replacement animals with the expectation that herd/flock immunity would develop over time. However, this has proved ineffective in some regions, and whole-flock/herd vaccination is now recommended in certain countries.

Vaccination of pregnant goats and sheep, especially in the second and third month of pregnancy, will result in abortion and the excretion of the living *B. melitensis* vaccine organism in the vaginal discharge and the milk. Consequently, the vaccine should not be used in pregnant animals or for 1 month before breeding. Vaccination of lactating animals may be followed by excretion of the organism in the milk for a short time. Reduced dose vaccination or conjunctival vaccination does not significantly reduce the risk of vaccine-induced abortions in pregnant animals, although reduced-dose Rev. 1 vaccination has been shown to provide protection for at least 5 years in endemically infected areas.

Conjunctival vaccination does decrease the period of seropositivity following vaccination. Vaccine efficacy and safety can vary with the manufacturer. National policies promoting widespread vaccination of sheep and goats with Rev. 1 vaccine have resulted in a significant reduction in the prevalence of small ruminant brucellosis and in the incidence rates of human brucellosis. However, Rev. 1 vaccine is also pathogenic to humans and its excretion, and persistence in milk following vaccination can result in human infection.

The general approach in endemically infected countries is to institute a whole-flock vaccination scheme followed by a young-stock vaccination until the prevalence of the disease is reduced, at which time test and slaughter can be implemented to eradicate the disease. This ignores the risk of adverse disease in the vaccinated animals and the risk for human infection from the vaccine strain. There is an urgent need for a nonviverrulent vaccine that induces seropositivity that can be differentiated from the seropositivity resulting from natural infection.

**Other Vaccines**

To circumvent the problem of persistent serologic response, ongoing efforts have been made to develop defined rough mutant vaccine strains that would be more effective against *B. melitensis*. Various studies have examined cell-free native and recombinant proteins as candidate protective antigens, with or without adjuvants. However, limited success has been obtained in experimental models with these, or with DNA vaccines encoding known protective antigens.

*B. abortus* strain 19 has been used for vaccination and appears to give protection that is as good as that achieved with the attenuated *B. melitensis* vaccine.

**REFERENCES**

**ABORTION IN EWEs ASSOCIATED WITH SALMONELLA ABORTUSOVIS**

*S. abortusovis* is a gram-negative rod-shaped aerobic bacterium of the family Enterobacteriaceae. The pathogen is highly adapted to sheep and is considered to be host specific for this species in which it can cause abortion. *S.Abortusovis* infection has a worldwide occurrence with a generally low prevalence. The infection appears to be more common in some European and Western Asian countries.

Transmission and spread of the infection occurs through infected animals that are introduced to flocks naive to the pathogen. The reservoir of infection is infected animals that do not abort. The organisms persist in internal organs of the asymptomatic carriers for up to 6 months and are excreted in the feces and vaginal mucus for periods up to 4 months. Infection can occur through the oral, conjunctival, or respiratory route, but oral ingestion is thought to be the main mode of infection. Venererel spread has been postulated, and rams certainly become infected, but all the evidence is against spread at coitus. Intrapreputial inoculation results in infection of rams and the passage of infected semen for up to 15 days.

The only significant clinical sign of *S. Abortusovis* infection is abortion, which is common during the second half to last third of gestation. Lambs may also be stillborn or die within the first day of life. Mortality in lambs is common from either weakness and ensuing hypothermia and hypoglycemia or to the development of acute pneumonia in previously healthy lambs up to 2 weeks old.

In flocks naive to the infection, introduction of the pathogen can cause abortion storms, with up to 60% of ewes aborting generally in the last trimester of gestation. Ewes rarely develop clinical signs, although some may transiently have a fever or develop post-abortive endometritis with vaginal discharge. Septic metritis and peritonitis in dams has been associated with deaths among ewes. Spread of the disease is strongly associated with the presence of aborting ewes and subsequent heavy environmental contamination. In flocks where the pathogen is endemic, abortion occurs sporadically, mainly affecting primiparous and newly introduced ewes. The infection appears to induce a strong immune response preventing abortion during the following pregnancies.

Identification of the disease depends on isolation of the organism, which is present in large numbers in the fetus, placenta, and uterine discharges. Use of PCR to identify *S. Abortusovis* is feasible because the organism has an IS200 element in a distinct chromosomal location. The resulting PCR assay has high specificity for *S. Abortusovis*, effectively
discriminating it from other S. enterica serovars. The disease can be diagnosed in fetuses by using a coagulation test on fetal stomach contents. The test had a sensitivity and specificity of 100% and 90% in a small number of samples.

Serologic tests to detect antibody to S. abortusovis include the SAT, hemagglutination inhibition, complement fixation, indirect immunofluorescence, gel immunodiffusion, and ELISA.

A strong immunity develops after an attack, and an autogenous vaccine has shown good results in the control of the disease. The results of vaccination need to be very carefully appraised because flock immunity develops readily and the disease tends to subside naturally in the second year.

The clinical findings in S. Dublin infections in ewes are very similar, and infection has become more important as a cause of abortion in ewes in the UK than S. Abortusovis. S. Ruiz has also been recorded as a cause of abortion in ewes, and ewes with salmonellosis associated with S. typhimurium may also lose their lambs. S. Brandenburg is a cause of illness and abortion in sheep, horses, calves, goats, and humans in New Zealand. Other differential diagnoses for abortion in ewes include chlamydioidis, brucellosis, campylobacteriosis, listeriosis, coxiellosis (Q-fever), and toxoplasmosis.

The administration of broad-spectrum antibiotics might aid in controlling an outbreak, but available reports are not generally encouraging. Chloramphenicol and the trimethoprim and sulfadiazine combination are considered effective for treatment, but use of chloramphenicol in animals intended for human food production is not permitted in many countries. A live S. typhimurium vaccine with optimal level of attenuation for sheep constructed by means of “metabolic drift” mutations was highly effective in preventing S. Abortusovis–induced abortions under field trial conditions. Subcutaneous and conjunctival vaccination with a live attenuated strain of S. Abortusovis confers immunity for at least three lambing periods. More recent vaccines, including those containing plasmid-cured strains of S. Abortusovis, are effective in preventing pregnancy loss in response to experimental challenge with wild-type S. Abortusovis.

To contain the spread of the infection during an outbreak aborted ewes should be isolated and abortion products that contain large amounts of bacteria must be destroyed. Disinfection of stalls and fomites with an agent with proven efficacy against Salmonella spp. is important.

ABORTION IN MARES AND SEPTICEMIA IN FOALS ASSOCIATED WITH SALMONELLA ABORTUSEQUI (ABORTIVOEQUINA) (EQUINE PARATYPHOID)

This is a specific disease of Equidae characterized by abortion in females, testicular lesions in males, and septicemia in the newborn.

ETIOLOGY
Salmonella abortusequi (abortivoequina) (also known as Salmonella enterica serovar Abortusequi) is a host-adapted serovar causing abortion in mares and donkeys. S. Abortusequi strains vary in virulence, with more virulent strains having greater in vitro cytotoxicogenicity. It is possible to determine the origin and progression of outbreaks of the disease by determining pulsed-field gel electrophoretic patterns of S. Abortusequi.

EPIDEMIOLOGY
The infection appears to be limited to horses and donkeys. Although widely reported in the early 1900s, this disease is rarely encountered and is one of the less common causes of either abortion or septicemia in horses. Recent reports of the disease are from Austria, Brazil, Croatia, Japan, and India, although the disease occurs in other countries. However, in the early 1990s, an outbreak of abortion occurred in a herd of 38 horses, in which 21 mares aborted between 5 and 10 months of gestation.

Natural infection may be caused by the ingestion of foodstuffs contaminated by uterine discharges from carriers or mares that have recently aborted. Transmission from the stallion at the time of service is also thought to occur. The infection may persist in the uterus and cause repeated abortion or infection of subsequent foals. Transmission from a female donkey to mares is reported with abortion a result in both species.

PATHOGENESIS
When infection occurs by ingestion, a transient bacteremia without marked systemic signs is followed by localization in the placenta, resulting in placentitis and abortion. Foals that are carried to term probably become infected in utero or soon after birth by ingestion from the contaminated teat surface or through the umbilicus.

CLINICAL FINDINGS
Abortion usually occurs at about the seventh or eighth month of pregnancy. The mare can show signs of impending abortion followed by difficult parturition, but other evidence of illness is usually lacking. Retention of the placenta and metritis are common sequelae and may cause serious illness, but subsequent sterility is unusual. A foal that is carried to term by an infected mare may develop an acute septicemia during the first few days of life or survive to develop polyarthritis 7 to 14 days later. Polyarthritis has also been observed in foals from vaccinated mares that showed no signs of the disease.

Infection in the stallion has also been reported with clinical signs including fever, edematous swelling of the prepuce and scrotum, and arthritis. Hydrocele, epididymitis, and inflammation of the tunica vaginalis are followed by orchitis and testicular atrophy.

CLINICAL PATHOLOGY
The organism can be isolated from the placenta, the uterine discharge, the aborted foal, and the joints of foals with polyarthritis. A high titer of Salmonella agglutinins in the mare develops about 2 weeks after abortion. Vaccinated mares will give a positive reaction for up to a year.

NECROPSY FINDINGS
The placenta of the aborted foal is edematous and hemorrhagic and may have areas of necrosis. The nonspecific changes of acute septicemia will be manifested in foals dying soon after birth; polyarthritis is found in those dying at a later stage.

Samples for Confirmation of Diagnosis
- Bacteriology: placenta, fetal stomach content, lung, culture swabs of joints (culture)
- Histology: formalin-fixed placenta, various fetal tissues including lung, liver (light microscopy)

TREATMENT
The antimicrobials recommended in the treatment of salmonellosis should also be effective in this disease.

CONTROL
Careful hygiene, including isolation of infected mares and disposal of aborted material, should be practiced to avoid spread of the infection. Infected stallions should not be used for breeding. In the past, when this disease was much more common than it is now, great reliance was placed on vaccination as a control measure. An autogenous or commercial bacterin, composed of killed S. Abortusequi organisms, was injected on three occasions at weekly intervals into all mares on farms in which the disease was enzootic, commencing 2 to 3 months after the close of the breeding season. A smaller dose (5 mL) of vaccine of higher concentration is as effective as a larger dose (20 mL) of vaccine of lower concentration. A formalin-killed, alum-precipitated vaccine is considered to be superior to a heat-killed, phenolized vaccine. In China, a virulent strain vaccine is credited with effective protection after two injections 6 months apart.

FURTHER READING

REFERENCE
The widespread use of vaccines and hyper-immune sera is credited with the almost complete eradication of the disease in developed countries.

**CHLAMYDIAL ABORTION (ENZOOTIC ABORTION OF EWES, OVINE ENZOOTIC ABORTION)**

**ETIOLOGY**  
*Chlamydia abortus* (previously known as *Chlamydothila abortus* and *Chlamydia psittaci* biotype 1/serotype 1) has a tropism for ruminant placenta and causes the disease commonly referred to as ovine enzootic abortion (OEA). The organism causes a similar disease in goats, and although this organism also can produce abortion in cattle, pigs, and horses, abortion associated with this organism is not common in these species. There is considerable genetic diversity among strains that cause abortion.

**EPIDEMIOLOGY**  
**Occurrence**  
The disease is one of the most common causes of diagnosed abortion in sheep and goats in the UK, Europe, Asia, the United States, and other countries. In the UK, it accounts for approximately 45% of abortions, and it is particularly common in lowland flocks that are intensively managed at lambing. However, its importance varies from country to country. It is an uncommon cause of abortion in Northern Ireland, and the disease does not occur in Norway, Australia, or New Zealand.

There have been several studies of seroprevalence in Europe that show a high seroprevalence in both domestic and wild ruminants but, until recently, most surveys have used the complement fixation test (CFT), which is not specific for *C. abortus*; therefore, the true seroprevalence of *C. abortus* in many countries is not well established.

**Source of Infection and Transmission**  
Infection is introduced into a flock by the purchase of latently infected replacements that usually abort at the end of their first pregnancy. Within a flock, the major source of infection is the placenta and the uterine discharge of aborting ewes. The main routes of transmission of *C. abortus* are oral or nasal: either ingestion of organisms shed in vaginal fluids and placental membranes at the time of abortion or lambing, or the inhalation of aerosols from contaminated areas. Pasture and the environment are contaminated by vaginal discharges, placenta, and aborted fetuses, and infected ewes shed the organism for a week before aborting and 2 weeks afterward. The elementary body of *C. abortus* is resistant to both physical and chemical influences, because it is metabolically inactive and the rigid cell envelope is osmotically stable and poorly permeable. Consequently, the organism is thought to survive for several days on pasture and longer in cold weather.

Infection of the ewe lamb may occur at birth, shortly following, or at subsequent lambing periods. Infection of pregnant ewes in early or midgestation results in either abortion in the final 2 to 3 weeks of gestation or the birth of stillborn or weak lambs that frequently die in the first few days of their life. Abortion always appears in the last weeks of gestation regardless of the time of infection. Infection of ewes in the last 5 to 6 weeks of pregnancy usually leads to the development of a latent infection, in which ewes appear to be uninfected until the next lambing season, when they abort. Thus late pregnant sheep may be infected by contact with aborting ewes, but usually do not abort until the next lambing season.

The common pattern of infection and disease is the small number of abortions in year 1 following the introduction of infected replacement ewes and then an epidemic abortion storm, in which up to 35% of ewes abort in the last 3 weeks of gestation or give premature birth to weak or dead lambs. After aborting, ewes develop a protective immunity and, in endemically infected flocks, 5% to 10% of the ewes abort annually. Surviving lambs born to infected mothers may be affected by enzootic abortion in ewes (EAE) in their first pregnancy.

Sheep that have aborted, subsequently rebred successfully, do not have further abortions, and the organism is not present in the placenta or vaginal discharge of subsequent pregnancies. However, levels of immunity vary and some may excrete organisms at estrus or seasonally for up to 3 years.

In chronically infected sheep, persistent infection can be demonstrated in the endometrial cells of the reproductive tract, and the organism is excreted in vaginal fluids during estrus.

Vaginal challenge of ewes at breeding time will result in infection and subsequent abortion. Thus venereal or passive venereal transmission is a possible route of infection but is not common. Chronic infection of the male genital tissues has been recorded, and infection may impair fertility in both rams and bulls.

The epidemiology of abortion with this agent in cattle is unknown, but it may transmit to cattle from infected sheep on the same farm.

**Experimental Reproduction**  
The disease is readily reproduced experimentally. Following subcutaneous injection there are no signs of clinical disease other than a modest increase in rectal temperature for 2 days after infection. There is a systemic antibody response that peaks 2 weeks after infection and then decreases until just before abortion or parturition, during which there is a second increase in antibodies to *C. abortus*. Experimental infection at 70 to 75 days pregnancy can cause abortion in the last 2 to 3 weeks of pregnancy or the birth of stillborn or live lambs. There is variation in the severity of the placental lesions in experimental infections. Abortion is associated with severe placental lesions, but the reason for the variation in severity and fetal manifestations is not known.

**Economic Importance**  
In the UK, enzootic abortion is the most common infectious cause of abortion in lowland flocks that are intensively managed at lambing time and has a major economic impact on agricultural industries worldwide. There are no recent estimates, but losses in the UK were estimated in the early 1990s at £15 to £20 million per annum.

**Zoonotic Implications**  
There is some risk for people working with livestock, such as shepherds and abattoir workers, for respiratory infection with this organism. However, the major zoonotic risk is to pregnant women because of the ability of *C. abortus* to colonize the human placenta. Human infection in early pregnancy results in abortion, whereas later infection can result in stillbirth or preterm labor. Infection is probably oral, from infected hands or food following handling of infected sheep or goats, or contaminated fomites such as clothing. Practices at lambing, such as mouth to mouth resuscitation of weak lambs or bringing weak lambs into the house to be warmed, promote zoonotic spread. Consequently,
infected placentas and dead lambs should be handled using gloved hands and disposed of by burning or burial. The organism can be detected in the milk of both sheep and cattle, so consuming raw milk also poses a risk for zoonotic infection.

PATHOGENESIS
Following infection, it is thought that the organism resides first in the tonsil and is then disseminated by blood and lymph to other organs, although the site of latent infection is not definitely known. Release from the latent state during pregnancy is thought to be caused by immune modulation and leads to bacteremia and infection of the placenta. Despite being a key feature of infection with *C. abortus*, little is understood about the underlying mechanisms that result in latent infections. However, experimental intranasal infection of nonpregnant ewes with a low or moderate dose of organisms induced latent infection and subsequent abortion, whereas a higher dose stimulated protective immunity.

The organisms invade the trophoblast cells of the fetal cotyledon then spread to the intercotyledonal regions of the chorion, producing a necrotic suppurrative placenta and impairment of the maternal–fetal exchange of nutrients and oxygen, hence, fetal death and abortion. An inflammatory response in the fetus may also contribute to fetal death.

It is not known why, regardless of the time of infection, pathologic changes in the placenta do not commence before 90 days' gestation, or even as late as 120 days, although this coincides with the commencement of rapid fetal growth.

CLINICAL FINDINGS
There are generally no premonitory indications of the impending abortions, which occur in late pregnancy. Ewes suffer no obvious systemic effects, but retained placenta and metritis can occur in goats. A vaginal discharge, lasting up to 3 weeks following the abortion, is common. Additional losses are caused by stillbirths and weak-born lambs and kids that die soon after birth.

In cattle, the infection causes abortion in the last third of pregnancy. Infected calves born alive may show lethargy, depression, and may be stunted. Mixed infections with *C. abortus*, *C. suis* and *Chlamydia* like organisms (*Parachlamydia* and *Waddlia* spp.) are recorded in cattle and associated with abortions featuring necrotic placentitis, but the true prevalence and significance of these infections is not clear.

CLINICAL PATHOLOGY
If the flock history and placental lesions suggest OEA, smears from affected and adjacent chorionic villi of the placenta can be appropriately stained (e.g., Giemsa or modified Ziehl–Neelsen) and examined under high magnification. Single or clumps of small, coccoid elementary bodies (300 nm) will stain red compared with blue cellular debris. Vaginal swabs from recently aborted ewes and smears of the fleece of uncleaned lambs or fetal abdominal contents can also be examined but contain fewer organisms. The organisms appear similar to *Coxella burnetii*, the agent of coxiellosis (Q fever), so this is not a definitive test.

Commercial antigen detection kits (fluorescent antibody test [FAT] and ELISA) are available but do not discriminate between Chlamydial species. Chlamydial DNA can be amplified by conventional or real time RT-PCR. These are highly sensitive, but can result in false positives if samples are cross-contaminated or false negatives if samples contain PCR-inhibitory substances. RT-PCR is rapid and relatively easily standardized and can demonstrate the DNA of *C. abortus* in tissues and swabs, such as of vaginal fluid, conjunctivae, and fetal membranes. A number of multiplex PCR tests are described and can differentiate between Chlamydiad species and other agents of infectious abortion, such as *Toxoplasma gondii* and *C. burnetii*. *C. abortus* can be isolated in embryo-nated chicken eggs or cell culture, but most diagnostic laboratories do not do this because of the zoonotic risk and requirement for level 2 biocontainment.

Infection in aborting animals can be demonstrated by rising serolog tic titers in paired serum samples collected 3 weeks apart. The CFT is commonly used but has only moderate sensitivity and is not specific because of common antigens shared with other Chlamydiad and some gram-negative bacteria. It will also be positive in vaccinated animals. Ambiguous results, such as suspected false-positive tests in flock accreditation programs or export testing, can be analyzed further by a Western blot using specific antigens.

A number of research and commercial ELISA tests have been developed. Those based on whole-cell or extracts of chlamydial elementary bodies have better specificity than the CFT but are less sensitive. Those based on segments of the outer membrane protein (OMP) or synthetic peptide antigens have greater sensitivity and specificity and are now more frequently used in diagnostic, epidemiologic, and seroprevalence studies.

Vaccinated animals will react to the currently used serologic tests, but wild-type and vaccine strains of *C. abortus* can be differentiated by PCR-restriction fragment length polymorphism (RFLP). This has provided evidence that the temperature sensitive mutant strain 1B used in vaccines is associated with ovine abortions in Scotland.

NECROPSY FINDINGS
Aborted fetuses typically have no gross abnormalities. Fetal fluid may contain chlamydial antibody and, although less sensitive than either isolation in McCoy cells or detection of chlamydial LPS antigen, can be useful when placenta is not available. Histologically, there may be mononuclear cell infiltration of hepatic portal areas and multifocal areas of hepatitis. The placenta is critical for diagnosis of chlamydial abortion in both cattle and sheep.

Placental cotyledons are necrotic and hemorrhagic, and the intercotyledonal areas are thickened, edematous, and leathery. This is in direct contrast to the targeting of cotyledons seen with toxoplasmosis. Chlamydial organisms can be seen in tightly packed sheets within the cytoplasm of swollen trophoblasts in formalin-fixed tissues or in direct placental smears using modified Gimenez, Koster’s, or other appropriate stains. Well-preserved, fresh placenta should be examined because the organisms are difficult to demonstrate in the fetus. Immunohistochemical stains perform well on formalin-fixed specimens. Most laboratories are reluctant to culture *Chlamydia* spp. because of their zoonotic potential.

Samples for Confirmation of Diagnosis
- **Bacteriology**: chilled liver, lung, placenta (cytology, PCR, ELISA)
- **Histology**: fixed placenta, liver (light microscopy, IHC)

The zoonotic potential of this organism means care needs to be taken when handling potentially infected material, and specimens should be properly packaged when submitted to a laboratory.

Differential Diagnosis
Other causes of abortion in cattle and ewes are given in Tables 18-1 and 18-2.

CONTROL
Ewes that have aborted should be isolated from the rest of the flock. There should be proper hygiene of the lambing areas, including disposal of bedding and aborted materials, and disinfection of pens with intensive lambing systems. Long-acting oxytetracycline has been used at 20 mg/kg IM in early pregnant sheep within an aborting flock to reduce subsequent abortions. However, treated ewes still shed the organism in vaginal discharges, and treatment at 10-day intervals may be needed.

Vaccines
Killed and live attenuated vaccines are available, but none are fully protective. Killed vaccines, composed of egg-derived or tissue culture organisms of one or two strains have been used for several decades. They are variably effective, but can reduce the frequency of abortion and shedding of the organism. However, outbreaks have occurred in vaccinated sheep, with strain variation a possible

**Nutritional:** Ingestion of excessive amounts of performed estrogens in the diet may cause abortion. There are usually accompanying signs due to increased vascularity of the udder and vulva. Possible dietary factor in so-called lowlands abortion.

**Isooimmunization:** Has not been observed to occur naturally in cattle. It has been produced experimentally by repeated IV injections of blood from the one bull of pregnancy. Intravascular hemolysis occurs in the calves.

**Unknown:** 30%–75% of most abortions examined are undiagnosed. The ingestion of large quantities of pine needles is suspected as a cause of abortion in range cattle in the United States. Infection with *Ureaplasma* and *Mycoplasma* spp. are other causes of undetermined relative importance.

**ELISA,** enzyme-linked immunosorbent assay; **IFAT,** indirect fluorescent antibody test; **PCR,** polymerase chain reaction.
COXIELLOSIS (Q-FEVER)

SYNOPSIS

Etiology  
Coxiella burnetii.

Epidemiology  
High seroprevalence in ruminants. Latent infection with recrudescence and excretion at parturition. Infection by direct contact and inhalation. Persists in the environment. Important zoonotic disease.

Clinical findings  
Infection in ruminants is common. Clinical disease is less common and presents mainly as abortion in sheep and goats.

Necropsy findings  
Placentitis. Organisms demonstrable in placental trophoblast cells by fluorescent antibody.

Diagnostic confirmation  
Fluorescent antibody staining and PCR of aborted material and vaginal discharge. Acid-fast rodlike organisms in stained impression smear of placenta. Serology (ELISA, CFT, immunofluorescent antibody) or bulk tank milk test to establish herd infection status.

Control  
Vaccination possible in many countries. Isolation of aborting ruminants. Destruction of bedding and straw contaminated with birth fluids.

Zoonotic aspects  
Infection of humans can vary from asymptomatic to severe and even fatal. Presents mainly as a mild influenza-like illness with pneumonia, but chronic infections can have serious outcomes, including endocarditis and osteoarticular disease. Mainly follows contact with sheep and goats around parturition rather than cattle.

CFT, complement fixation test; ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

ETIOLOGY

Coxiellosis (Q fever) is a zoonosis associated with C. burnetii, which is an obligate intracellular parasite classified within the family Coxiellaceae (formerly Rickettsiaceae). It can be divided into six genotype clusters on the basis of RFLP, although different methods can be used such as multiplex sequence typing (MST) or MLVA, which can identify up to 17 different microsatellite markers. The presence or absence of specific genotypes could explain inconsistencies in reports on the effects of coxiellosis, particularly on reproduction in cattle. Coinfection with multiple genotypes can occur, although a large study of milk samples in the United States identified predominantly genotype ST20 in bovine milk and mainly ST8 in caprine milk, whereas ST20 was associated with an abortion storm in a goat dairy in the UK, and ST33 with the large outbreak in the Netherlands. Unlike other rickettsiae, C. burnetii it is quite resistant to environmental influences and is not dependent on arthropod vectors for transmission. It displays two antigenic phases or phenotypes: Phase 1 is more infectious and able to replicate in the host, and Phase 2, which is unable to replicate (these phases correspond to the smooth and rough phases of other gram-negative bacteria, respectively).

EPIDEMIOLOGY

Occurrence  
The organism has worldwide distribution, although serologic surveys have found no evidence of infection in New Zealand. C. burnetii cycles in a wide variety of wildlife species and their ectoparasites. The infection also cycles in domestic animals; cattle, sheep, and goats are the main livestock reservoirs of infection for humans. Rates of infection in farm animals vary considerably between locations, between countries, and with time, because there appears to be cycles of infection within regions.

There can be a wide range in the seroprevalence of Q fever within regions and within individual herds or flocks. In cattle, from 4% to 100% of herds have been reported as positive (either seropositive or bulk milk test), and the within-herd prevalence varies from 0% to 49%.6 The flock and within-flock prevalence in sheep and goats shows similar ranges and, as for cattle, varies according to year and region.5,6 There is little information on management or other factors that might influence this variation in prevalence, but one study found a significantly higher prevalence in housed cattle compared with cattle kept on pasture. Analysis of data from 69 publications found the overall mean prevalence to be slightly higher in cattle (estimate of 20% and 38% for herd and within-herd prevalence, respectively) than for small ruminants (sheep and goat; 15% and 25% for flock and within-flock prevalence, respectively).5,6 The prevalence in flocks of dairy goats and dairy sheep is much higher than in nondairy flocks.

Source of Infection and Transmission

Infection and transmission is by direct contact and by inhalation. Infection of nonpregnant animals is clinically silent and is followed by latent infection until pregnancy, at which time there is recrudescence with infection in the intestine, uterus, placenta, and udder and excretion from these sites at parturition. The organism is present in high concentration in the placenta and fetal fluids and subsequent vaginal fluids, is also excreted in urine, and is present in the feces of sheep from 11 to 18 days postpartum. In a longitudinal study in a naturally infected sheep flock in France, the number of C. burnetii was higher in vaginal mucus and feces compared with milk, peaked 3 weeks after abortion or birth, and was highest in primiparous and aborting ewes. Shedding of C. burnetii in the feces can be persistent, so this can contribute significantly to environmental contamination with the organism. Infection can result in abortion, stillbirths, or poorly viable lambs, but the neonates of infected, excreting ewes are often born clinically normal.

Abortion usually does not occur at successive pregnancies. However, there can be recrudescence of infection and excretion at these pregnancies, especially the one immediately following, and reproductive failure at a second consecutive pregnancy is recorded in goats.2 Goats excrete the organism in vaginal discharges for up to 2 weeks, it is present in milk for up to 52 days after kidding, and is also found in the feces. It also strongly adheres to the zona pellucida not removed by standard washing procedures. Thus the possibility of transfer of C. burnetii by embryo transfer cannot be ruled out.9

In cattle, maximum shedding also occurs at 1 and 2 weeks following parturition, the organism is excreted in milk for at least
several months and can be detected for up to 2 years in bulk tank milk. Abortion in cattle is less common than in goats and sheep and is sporadic rather than occurring as abortion storms like occur with sheep and goats. The organism is present in the semen of seropositive bulls, and venereal transmission is suspected.

There is a significant contamination of the environment of infected animals at the time of parturition and abortion. This is a major risk period for transmission of the disease within herds and flocks and presents a significant zoonotic risk. The organism is still present in large concentrations in soil 12 months after outbreaks of coxiellosis on goat farms.10

Pathogen Risk Factors
C. burnetii is very resistant to physical and chemical influences and can survive in the environment, manure, and soil for several months. It can resist common chemical disinfectants but is susceptible to sodium hypochlorite, 1:100 Lysol solution, and formalin fumigation provided a high humidity is maintained.

There is strain variation in the organism, and differences in genotypes and DNA sequences have been correlated with differences in the type of disease occurring in humans and domestic ruminants. The organism is highly infectious, with the infective dose for humans estimated to be one organism.

Zoonotic Implications
In humans infection is primarily by inhalation. Sources of infection include such diverse materials as soil; airborne dust; wool, bedding; and other materials contaminated by urine, feces, or birth products of animals. The potential for human infection from these sources is substantial (e.g., ovine manure used as a garden fertilizer has been incriminated).

Sheep and goats have traditionally been identified as the major reservoir of infection for humans, and the location of urban populations in proximity to large dairy goat herds was a significant reservoir in the Dutch outbreak from 2007 to 2010.1

The organism is present in the milk of infected cattle, sheep, and goats. A significant proportion of seropositive cattle excrete the organism in milk, and periods and duration of excretion are variable but may persist at least 2 years. C. burnetii is destroyed by pasteurization but there is a risk for people who consume raw milk, particularly unpasteurized milk from sheep and goat.

Rates of seropositivity in humans vary markedly between surveys, but there is a higher rate of seropositivity in people that are associated with domestic animals and their products and with farm environments (such as farm workers, veterinarians, livestock dealers, dairy plant and slaughterhouse workers, and shearers).3

Many instances of infection in humans have been linked to exposure to parturient sheep and goats. A spectacular example is the 2007 to 2010 epidemic in the Netherlands, in which over 3000 notifications of human disease were analyzed and only 3.7% of people had worked in agriculture or slaughterhouses.11 This outbreak was attributed to airborne transmission of contaminated dust originating from dairy goat farms located in densely populated areas. The number of human cases abruptly declined after control measures were implemented on the goat and sheep farms, including vaccination, the mass culling of more than 50,000 pregnant does and ewes on infected farms to reduce shedding of the organism, and mandatory PCR testing of bulk tank milk for C. burnetii.11 Living close (<2 km) to a large dairy goat farm that had an abortion storm caused by Cxiella burnetii was identified as the major risk factor for human cases during the Netherlands epidemic.12

Coxielliosis in humans is referred to as Q-fever and is often asymptomatic, but can result in acute disease characterized by fever, general malaise, headache, and less commonly, pneumonitis, hepatitis, and meningoencephalitis. Endocarditis, hepatitis, and osteoarticular diseases are manifestations of chronic disease in around 2% of human infections.1 Those at most risk of chronic disease are immunocompromised individuals and pregnant women. There is a concern that the prevalence of infection in farm animals is increasing and spreading geographically, so that there is a greater risk for human infection, particularly when dairy farms are located near urban populations. Epidemics of human infection have been documented in several countries including Australia, France, Germany, the United States, Bulgaria, the UK, and the Netherlands.11

C. burnetii is considered a potential agent for bioterrorism because of its survival in the environment, the ease with which it can be transmitted by aerosol and wind, and the very low infectious dose.

CLINICAL FINDINGS
Infection of ruminants can occur at any age and is usually clinically inapparent. In the experimental disease in cattle, anorexia is the only consistent clinical finding. C. burnetii is a cause of abortion storms and sporadic abortion in sheep and goats but only rarely associated with sporadic abortion in cattle.13 Abortion occurs during the latter part of pregnancy in individual does or ewes, usually with no sign of impending abortion.

In the 2007 to 2010 epidemic in the Netherlands, abortion storms were reported on 28 dairy goat and 2 sheep dairy farms, with up to 60% of goats aborting compared with an average of 5% abortions on the sheep farms.13

CLINICAL PATHOLOGY
There are a number of serologic tests, including complement fixation, microagglutination, ELISA and indirect immunofluorescence, and PCR (both conventional and quantitative real-time PCR). A comparison of these tests concluded a combination tests was preferable, such as ELISA for serology and PCR for detection of DNA of the organism.14

The immunofluorescence assay is used as the seroreference test for the serodiagnosis of coxiellosis. It can detect antibody to phase variants and can provide epidemiologic information because Phase 1 antibody is associated with recent and acute infections and Phase 2 antibody with chronic infections.

Conventional and quantitative real-time PCR tests can be conducted on bulk tank milk and are a useful means of monitoring herd or flock prevalence within regions and outbreaks within herds or flocks.15,16

NECROPSY FINDINGS
There are seldom gross lesions in aborted fetuses, but foci of necrosis and inflammation are occasionally seen in the liver, lung, and kidney microscopically.17 The placenta from aborting animals is usually thickened and a purulent exudate or large, red-brown foci of necrosis is typically seen in the thickened intercotyledonal areas. Microscopically, large numbers of nectroic neutrophils are usually visible on the chorionic surface, and swollen trophoblasts filled with the organisms can also be found in well-preserved specimens. This is consistent with bacterial replication occurring only in the trophoblasts of placenta, and not in other organs, of experimentally infected pregnant does and their kids.17 Examination of placental impression smears stained with Gimenez, Koster’s, or other appropriate techniques provides a means of rapid diagnosis. However, care must be taken to avoid confusing Cxiella-infected trophoblasts with cells containing Chlamydiophila organisms. Coxiellosis can be confirmed by PCR, fluorescent antibody staining of fresh tissue, or immunohistochemical staining of formalin-fixed samples. In most laboratories, culture is not attempted because of the zoonotic potential of this agent.

Samples for Confirmation of Diagnosis
• Bacteriology and detect DNA: chilled placenta (fetal liver and spleen) (cytology, FAT, PCR)
• Histology: fixed placenta and fetal lung, liver, kidney (light microscopy, immunohistochemistry)

Note the zoonotic potential of this agent when handling aborted material and packaging and submitting specimens.
significant reduced risk of shedding in vaginal mucus, uterine fluids, milk, and feces of vaccinated goats exposed to infection compared with controls. However, it was concluded that there was no reduction in the risk or amount of shedding in vaccinated ewes compared with unvaccinated ones. Vaccination of humans has reduced infection rates in high-risk groups and is used in the appropriate circumstances in Australia, such as workers on goat and sheep dairy farms, abattoir workers, veterinarians, and veterinary students.

During a natural outbreak of coccidioidomycosis in a dairy flock, two treatments with oxytetracycline at days 100 and 120 of pregnancy failed to reduce shedding of the organism in vaginal fluids, milk, or feces compared with untreated ewes. In this flock, vaccination for three consecutive seasons reduced the proportion of ewes shedding the organism to around 4%. Pasteurization of milk that is consumed fresh is preferable, but veterinarians dealing with herds that provide raw milk should ensure that these herds are seronegative or bulk tank milk is PCR negative for C. burnetii. In a study of manufactured dairy products in France (mainly cheese, but also yogurt, cream, and butter), the DNA of C. burnetii was detected in 64%, but no viable organisms were recovered. A greater proportion of food products from large-scale manufacturers were positive compared with artisan food.

**REFERENCES**

**DIFFERENTIAL DIAGNOSIS**

- Other causes of abortion in sheep and goats (Campylobacter, Chlamydia, and Toxoplasma, Table 18-1).
- The diagnosis of the disease in farm animals, other than abortion, suspected as associated with this agent is difficult and relies on the detection of the organism.
- A positive serologic test in an animal or herd is indicative of infection at some time but does not indicate an association with the problem at hand.
- PCR or PCR-ELISA has been used for detection of the organism in milk.

DISEASES OF THE GENITAL TRACT ASSOCIATED WITH MYCOPLASMA SPP.

Vulvovaginitis in cattle, sheep, and goats may be associated with *Mycoplasma agalactiae* var. *bovis*. The same infection, when introduced with semen into the uterus, can cause endometritis and salpingitis, resulting in temporary infertility and failure to conceive. Persistent infection of the genital tract of bulls has also been produced experimentally.
